filter coefficients with \( N_f = 16 \). Once the wavelet packet decomposition had been formed, the best basis (optimal tree) was determined from the energy maps. The criterion used to form the best basis was the symmetric entropy criterion (Equation 19). Figure 11 marks the best basis selected by the LDB algorithm for each of the sets of data. For the \( p \)-xylene data, the selected best basis was the original data.

Once the best basis had been found, a subset of WPCs was selected from the best basis. It was decided to select the 16 WPCs based on the same discriminant measure which produced the best basis, i.e. symmetric entropy.

The asterisks in Figure 11 show the positions of the 16 WPCs which were selected from the best basis and supplied to the classifier BLDA. The WPCs are quite clustered, which is a likely consequence of selecting the coefficients by a univariate strategy, that is without consideration being given to previously selected features. There is also a tendency for the WPCs to be largely selected from band(4,0) and band(4,1) of the WPT. These bands contain the same coefficients as those in band(4,0) and band(4,1) from the DWT. It should be noted, however, that in Figure 10 there is only one coefficient selected from either of these bands (see mineral data). The conflict in feature selection is a likely consequence of using different selection strategies for selecting features.

The sixteen WPCs with the largest symmetric entropy measures were supplied to the BLDA classifier in a top-down approach using the first 1, 2, ..., 16 coefficients for classification. That is, initially a single WPC (with the largest discriminant measure) was supplied to the classifier. Then, the two WPCs with the largest discriminant measures were supplied to the classifier. This procedure continued until all 16 coefficients had formed part of the BLDA model.

Table 8 gives the classification rates for the training and testing data for each of the discriminant data sets where the first 1, ..., 16 WPCs were selected from the best basis, and supplied to BLDA. The numbers in bold type had the largest (test) CCR and the fewest terms in the discriminant model. This application of the LDB approach closely followed that outlined by Saito and

INFRARED SPECTROSCOPY

5.2.7 Adaptive Wavelet Algorithm

Previous feature extraction methods involving the DWT were performed using filter coefficients from the Daubechies family. Many filter coefficients could have been chosen, but the Daubechies filter coefficients were chosen as they tend to be popular. There is no reason, however, that another set of coefficients could not have been chosen. Of course, the problem lies in deciding whether or not better results might be obtained using another set or family of filter coefficients. In this section, task-specific filter coefficients are designed using the AWA described in section 4.3. The underlying principle of the AWA is to avoid deciding which set of filter coefficients to use, and instead to design the filter coefficients to suit the task in hand, which in this case is discriminant analysis.

The AWA is applied using several settings of the \( m \), \( q \), and \( j_0 \) parameters, where \( j_0 \) is the lowest level of the DWT and \( N_f = m(q + 1) \). The particular \( (m, q, j_0) \) triplets used were \((4,3,2), (4,2,2), (8,1,1), (2,5,3), (2,5,4), (2,7,3), \) and \((2,7,4)\). These settings were chosen because (1) they provide suitable ratios of the dimensionality of the wavelet bands to the sample size and, (2) the number of filter coefficients is of reasonable size. We considered \( N_f = 12 \) and \( N_f = 16 \). Mallet et al.\(^{(21)}\) describe some heuristics for choosing these parameters.

The discriminant criterion function implemented by the AWA is the CVQPM criterion function. A form of banded selection was performed, whereby the CVQPM was calculated from a band of coefficients. The same coefficients were later supplied to the classifier. The value \( \tau \) was chosen as the band which gave the highest CVQPM value at initialization for a particular \( (m, q, j_0) \) triplet. For more details on this banded selection process see Mallet et al.\(^{(21)}\)

The settings which produced the highest test CCR are displayed in Table 9 for each of the data sets. The AWA performed consistently well for each data set. It is interesting to note that for three of the four data sets the more common \( m \) \( = 2 \) band DWT was used.

6 SUMMARY OF RESULTS

This section summarizes the results of the various classification procedures which were accumulated in section 5. Figure 12 displays the CCRs for each of the classification strategies. Only the CCRs for the testing data are displayed. To enable easier interpretation of Figure 12, crosses have been used to indicate the results of the high-dimensional methods, circles have been used to indicate the low-dimensional classification performed on the original data, and the asterisks indicate the low-dimensional classification methods based on the coefficients from the DWT. To
further enhance interpretation of Figure 12, the line types also change with the marker indicators. Table 10 shows the actual CCRs for the training and testing data sets.

The most salient issues that have arisen from the comparative analysis are as follows.

- RDA tends to outperform the other high-dimensional classifier PDA, with the exception being for the mineral data where PDA outperforms RDA.

- If RDA is compared with the low-dimensional methods which entail some form of feature extraction (or selection), then it can clearly be seen that RDA also consistently produces high classification results across each of the sets of data. For the mineral data, however, RDA is outperformed by three of the wavelet-based approaches (and PDA).

- For the classification methods SBLDA, SBQDA and FDA there does not appear to be any one approach that consistently performs well.

7 CONCLUSION

This paper has presented several different strategies that can be used for classifying spectral and similar forms of data. We considered two main approaches – using a high-dimensional classifier for all of the original data, and using a low-dimensional classifier on selected features. The features considered were the original variables, and coefficients from the DWT were also explored. The objective of this paper was to compare the performances of each of these strategies. Based on the CCR it was noted that the high-dimensional classifier RDA performed consistently well. It was difficult to observe if any low-dimensional classifier consistently produced outstanding performances. This subjectivity arose due to the different feature selection strategies which were implemented in conjunction with the classifiers BLDA, BQDA and FDA. However, the AWA did consistently produce high CCRs and compared favourably with RDA. This demonstrates that it can be advantageous to design your own task-specific filter coefficients.

Throughout this paper, much attention has been focused on the CCR for comparing techniques. It should be mentioned that there are many other attributes which should be addressed when comparing techniques. Computational complexity is one item which should be considered. Although a comprehensive analysis of computational complexities was not undertaken, in our experience RDA and the AWA tend to be much more computationally expensive than the remaining methods. This is obviously due to the optimization routines which form part of these techniques.

Another attribute is the qualitative information and interpretability that can be obtained from the models. For example, whether the model can discover which variables are more important, or whether the model has graphical capabilities for exploring group separation, for instance. The Bayesian classification methods BLDA, BQDA and RDA are difficult to interpret qualitatively. However, when BLDA and BQDA are combined with stepwise methods then some insight into discriminatory regions of the data is obtained by noting which variables have been selected. This is the case whether selection is from the original data or from wavelet coefficients. The wavelet procedures which involve a banded selection of coefficients do not allow for easy interpretation, although if FLDA was applied to these features then one could examine the size of the discriminant coefficients to indicate which coefficients are more important. A useful feature of both PDA and FDA is that these methods can generate discriminant plots.

To provide more detailed comparisons, further work on more data sets, including simulated data, needs to be performed. Here we have simply introduced some traditional and modern methods for classifying spectral data and quantitatively examined their performances using the CCR, to help provide the reader with more insight into these techniques.

ABBREVIATIONS AND ACRONYMS

AWA  Adaptive Wavelet Algorithm
BBLDA  Banded Bayesian Linear Discriminant Analysis
BBQDA  Banded Bayesian Quadratic Discriminant Analysis
BLDA  Bayesian Linear Discriminant Analysis
BQDA  Bayesian Quadratic Discriminant Analysis
CCR  Correct Classification Rate
CVQPM  Cross-validated Quadratic Probability Measure
DWT  Discrete Wavelet Transform
FDA  Flexible Discriminant Analysis
FLDA  Fisher’s Linear Discriminant Analysis
FT  Fourier Transform
LDB  Local Discriminant Basis
MARS  Multivariate Adaptive Regression Splines
NIR  Near-infrared
PDA  Penalized Discriminant Analysis
PLSR  Penalized Least Squares Regression
QPM  Quadratic Probability Measure
RDA  Regularized Discriminant Analysis
SBLDA  Stepwise Bayesian Linear Discriminant Analysis
SBQDA  Stepwise Bayesian Quadratic Discriminant Analysis
SWBLDA  Stepwise Wavelet Feature Extraction Using Bayesian Linear Discriminant Analysis
SWBQDA  Stepwise Wavelet Feature Extraction Using Bayesian Quadratic Discriminant Analysis

Spectral Databases, Infrared

Barbara J. Dębska and Barbara Guzowska-Świder
Rzeszów University of Technology, Rzeszów, Poland

1 Introduction

Infrared (IR) spectroscopic analysis is one of the most important means of structure determination of organic compounds because it can provide much information about the molecular structures of compounds. Innumerable IR spectra have been measured since the Coblentz collection was published in 1905 and many catalogs (printed collections and, further, computer IR databases) have been developed. These experimental data were very useful in the structure elucidation process, and many studies have been conducted on the relationships between various organic functional groups and their absorption bands. Usually, chemists make structural analyses using two methods. One method is to search a library of standard spectra and to find the closest match to the unknown spectrum [library search (LS) Method]. The other method is to find characteristic spectral features (connected with some parts of a chemical molecule), which is based on the empirical examination of a large number of spectra of known compounds. The conventional process of structure elucidation can be time-consuming, especially in the case of complex, multifunctional compounds. Computers offer the promise of enhanced human productivity in this field. A number of systems for searching a collection of spectral data in order to find reference spectra, identical with or similar to a spectrum of an unknown compound, have been developed. The systems may also retrieve other information, such as molecular formulas, chemical names, Chemical Abstracts Service (CAS) registry numbers, molecular fragments or complete structures of compounds. Most of the search systems are designed for a single type of spectra (e.g. IR spectra), but there are also some multimethod systems that apply various spectral techniques [IR, nuclear magnetic resonance (NMR), mass spectrometry (MS), Raman or ultraviolet/visible (UV/VIS)] to improve the results of a structure recognition process. The weakness of the LS approach is related to the necessity for a powerful computing system and a large database. Also, even a large database may not contain identical or highly similar reference spectra with respect to the sample spectrum. Thus the LS method can solve the problem of structure identification when the database contains a spectrum identical with (or highly similar to) the sample spectrum. Otherwise, to elucidate the structure of an unknown compound, it is necessary to use computer methods that permit the recognition of structural fragments present in the molecule of the analyzed substance. These programs use correlation tables (a list of structural fragments and their spectral characteristic parameters) that can form a knowledge database or be an integral part of the program. Usually, these parameters are taken from the literature, but they can also be generated from a computer library of IR spectra by computer-simulated neural networks, application of a statistical algorithm or other methods. There are systems for structure recognition which test a large number of spectral and structural features in order to calculate decision functions between the classes of compounds. When applied to a spectrum of an unknown structure, these functions indicate the presence or absence of the respective molecular fragments. Methods of this type include various cluster analyses, pattern recognition methods and computer-simulated neural networks.

The first collections of IR spectra (printed and computer IR databases) were often of poor quality, owing to the low technological level of the spectrometers used. Contemporary IR databases contain spectra of a considerably higher quality owing to the advent of high-resolution spectrometers and proper sample preparation (according to the standards required). Apart from large spectral
databases (SDBs) containing data on different chemical compounds, a large number of collections dedicated to specialized groups of compounds are offered. Recently, a new type of printed spectral catalogue has appeared on the market: the traditional form of a book is supplemented by a diskette containing peak tables in a digital format, allowing the reader to search for unknowns. As far as the computer databases are concerned, many efforts are aimed at the unification of spectral and chemical structure codes, which will assist an easy exchange of information between various scientific centers. The International Union of Pure and Applied Chemistry (IUPAC) has additionally published a very positive opinion about the Joint Committee on Atomic and Molecular Physical Data (JCAMP) format which makes it very probable that this format will be broadly used in future.

All the above-mentioned issues are discussed in this article, with detailed focus on (1) history of printed and computer IR collections, (2) more important IR databases, (3) standards in IR databases, (4) structure of IR databases, (5) monomethod identification of chemical compounds and (6) application of multimethod SDBs to structure elucidation.

1 INTRODUCTION

Recognition of a chemical structure, realized nowadays by spectroscopic methods, is very important in many research fields, e.g. in chemical analysis, organic synthesis (identification of main reaction products, determination of by-product chemical structures), pharmacology (recognition of the structure of pharmacologically active compounds, investigation of drugs and pesticides metabolism) and others. Irrespective of the applied spectral methods, the basic step in structure elucidation is the interpretation of the spectrum. This process is intellectually difficult, demands a professional education, experience and very often also intuition. For the interpretation of spectra, the chemist uses mainly semiempirical methods which are based on large amounts of previously accumulated reference data (spectra libraries, tables of spectrum–structure correlations). As searching through large collections of data and selecting and applying various empirical rules by conventional means is generally very time-consuming and often boring, many approaches to the computer-aided (semiempirical) interpretation of spectral data have been proposed. Three basically different techniques may be distinguished.

In the most commonly used method, called the LS method, the computer scans a reference spectra collection, comparing the spectrum of an unknown compound with each spectrum of a reference set. The structures of those reference compounds having spectral data most similar to the unknown are considered to be similar to the unknown (analyzed) structure. In the second method, the computer tests (learning phase) a large number of spectral and structural features in order to calculate a decision function between the classes of compounds. When applied to a spectrum of an unknown structure, this function indicates the presence or absence of the respective structural features (substructures, molecular fragments). Methods of this type include various cluster-analysis and pattern-recognition methods. Computer-simulated neural networks can also be acknowledged as a method of this type, although the classification function in the networks is unknown.

The third method is usually employed when the LS fails, i.e. there is a lack of spectra similar to the analyzed spectrum in the spectral library. In this method, spectrum–structure correlations generalized and condensed into a set of interpretation rules are applied to the interpretation of an unknown compound spectrum in order to predict whether the respective substructures are present or absent in the unknown molecule.

The above remarks refer to all kinds of spectra, especially to IR spectrometry. Computer IR SDBs were created before other computer SDBs. The experience gathered during the development of IR databases helped in creating SDBs for other spectral techniques. IR spectrometry was earlier the basic method for chemical structure identification, but later it became only a supporting method for NMR and MS. Nevertheless, most data banks contain IR spectral libraries.

2 HISTORY: MORE IMPORTANT INFRARED DATABASES

2.1 Printed Collections of Infrared Spectra

Before computer IR databases were developed, collections of IR spectra of pure chemical substances had been created in the form of printed catalogs. The first collection of IR spectra was published by Abney and Festing in 1881. This collection contained only 48 spectra. Then, in 1905–1908, Coblenz published his collection of IR spectra containing 135 organic compounds. The development of a quantum theory, wave mechanics and also the possibility of measuring substances at various temperatures and pressures and in different states of concentration indicated the great importance of IR spectroscopy in the investigation of molecular structures. Consequently, the number of IR spectra registered by different laboratories increased dramatically, so that various catalogs soon contained even several thousands of spectra. Until the early 1950s, IR collections were printed as books, unfixed sheets (card indexes), slides, microfiches
or microfilms. As the collections of IR spectra increased in content, searching for information became more and more laborious and arduous. Later, a noticeable improvement was obtained by application of cards perforated for spectra presentation and sorting machines to review separately card indexes. The first collections of this kind were elaborated by the American Wyandotte Chemical Corporation in cooperation with the American Society for Testing and Materials (ASTM), and the catalog created (comprising 150 000 IR absorption spectra) was constructed using standard Hollerith cards. Various spectra encoded on the cards contained information about band locations, chemical classification of the compound, its chemical formula and a classification number in the original (source) catalog. One year later, the Institute of Applied Spectroscopy in Dortmund and the Institute of Molecular Spectroscopy in London created and disseminated a collection of IR spectra known as the Document of Molecular Spectroscopy (DMS) catalog. The system of checking DMS cards was to give the answer to the question, “Is a spectrum of an unknown compound present in the card index or not?,” and was based on the possibility of defining some classification features, i.e. spectral parameters (the location and intensity of absorption bands at specified intervals), structural parameters (the presence of characteristic structural fragments, e.g. ring systems, substituents, functional groups) and general parameters (e.g. qualitative composition, molecular weight, melting point, boiling point). The classification features were perforated on the card borders (margins) of each collection element (for each chemical compound). As the system was based on punched cards, the searching process could be speeded up by application of electromechanical shakers. The DMS system had a symptomatic advantage, the possibility of setting up different parameters in a logical conjunction within one operation of card-index searching, i.e. to input into a searching matrix of a shaker a set of holes, corresponding to some selected features, to obtain transparency through the cards (i.e. the holes fit together). An example task is to search for “all cards containing an absorption band located in the 1800–1700 cm⁻¹ range, iodide atom and molecular weight below 420”. The system also allowed negative searching, i.e. taking into consideration the lack of a given feature.

The automation of searching through a card index considerably improved the use of catalogs. A user could obtain a reduced set of spectra according to declared earlier parameters, and subsequently look through the remaining spectra manually. In spite of the inconveniences of searching through a large set of spectra, printed catalogs are still acknowledged by chemists, and today handbooks containing IR spectra of chemical substances are still published. For example, books containing IR spectra are as follows: Raman/IR Atlas of Organic Compounds (~1000 IR spectra), The Aldrich Library of IR Spectra (~12 000 IR spectra), The Aldrich Library of FTIR (Fourier transform infrared) Spectra (~18 000 IR spectra), The Aldrich Library of FTIR Spectra: Vapor Phase (~6 550 IR spectra), The Aldrich Library of FTIR/Raman Spectra (~14 000 IR spectra), Coblentz Society Reference Spectra Collection (Volume I, 860 IR spectra; some contain only specified types of compounds, e.g. Coblentz Society Reference Spectra Collection, Volume II, 282 IR spectra of halogenated hydrocarbons; Volume III, 284 IR spectra of plasticizers and other additives, Atlas of Polymer and Plastics Analysis (~6 700 IR spectra), Handbook of Fourier Transform Raman and IR Spectra of Polymers (500 IR spectra) and An IR Spectroscopy Atlas for the Coatings Industry (740 IR spectra).

Some IR collections are published in the form of a WebBook (http://webbook.nist.gov/chemistry), e.g. National Institute of Standards and Technology (NIST) Chemistry WebBook (5 000 gas-phase IR spectra). Constantly updated information about books on IR spectra is available on an Internet website, e.g. http://wally.rit.edu/pubs/guides/spectra.html.

2.2 Computer Databases of Infrared Spectra

Developments in hardware technology afforded further progress in the field of SDB creation and the elaboration of algorithms used for searching and interpretation of stored data. The first databases containing IR spectra were coded on magnetic tapes or disks. The type of stored information was changing. It was possible to store not only data about absorption band parameters of the spectrum (see Table 1), but also to record the whole spectrum in a discrete form, which permitted the exact reproduction of a spectral curve (see Table 2).

Some more important computer IR databases, developed recently, are presented in Table 3. From the data in these tables, it can easily be concluded that some scientific centers elaborated not only one, but several computer IR databases. The reasons why various IR databases were developed in the same research center were, among others, the application of different sources of information to develop a spectral collection (e.g. SPECTRUM-I was created on the basis of a DMS card index, whereas SPECTRUM-II is based on the Sadtler catalog, Table 1), the use of various algorithms for spectral coding (e.g. ZAPAH and KISIK in Table 1, and three of the Sadtler databases cited in Table 2) and also the separation of certain spectra collections (e.g. a set of polymers in the POLYMER database, see Table 2).

Nowadays, there are two trends of computer database development, i.e. creating larger and larger collections...

Additionally, access to a small local Hoechst database was included (550 standard spectra, 500 spectra of substances supplemental for polymers, and 300 spectra in the vapor phase). The libraries of the central data bank were accessible only in a read-only procedure, whereas the resources of the second database were continually supplemented (about 25 spectra every week) by analytical laboratories connected to the network (Analytical Lab, Frankfurt; R&D Pigments, Frankfurt; Analytical Lab Kalle, Wiesbaden; Analytical Lab Hoechst, Gersthofen; and others), which produced high-quality spectra.

The analysis of the organization methods of IR databases permits their evaluation. For example, taking into consideration the ASTM catalog created over 30 years (1950–1980), containing at the time about 90 000 standards,(9) it can be stated that limitations imposed on the database at the time of its development (on perforated cards, with application of Hollerith cards with 80 columns) allowed archiving of only some selected bands (coded in micrometers), as opposed to collections containing full discrete spectra, which are nowadays coded in wavenumbers. An additional artifact of the ASTM catalog is the lack of the evaluation of spectrum quality and unclear terminology, e.g. using also some customary chemical names inconsistent with semantics, which led to a certain number of repeated spectra in the database (i.e. spectra of the same substance). The inconsistent terminology also excluded the possibility of cooperation between this database and other collections [e.g. carbon-13 nuclear magnetic resonance (13C-NMR), proton magnetic resonance (1H-NMR), MS, ultraviolet (UV)] which were created simultaneously with IR databases, and they stayed as monomethod manual

catalogs and related to computer libraries of molecular spectra.

Currently the world’s largest database of IR reference spectra of organic compounds is the Sadtler Condensed Phase IR Standards Database. This database contains data on 75 620 different chemical compounds (http://www.bio-rad.com/626559.html). The IR spectra stored in the Sadtler collection are of very high quality. Each compound, before its spectrum is placed in the Sadtler collection, is prepared under standard conditions at Bio-Rad Laboratories, Sadtler Division, using equipment manufactured by leading instrument makers. Samples are checked to ensure that nonlinearity is avoided to maximize reproducibility and provide for the best subtraction of reference spectra. Wherever possible, Sadtler chemists verify every IR spectrum by checking the corresponding NMR and UV spectra. Any spectra which show evidence of composition impurities or reaction with sampling apparatus are rejected. Each spectrum is then reviewed by an independent consultant before inclusion in the database. These quality control procedures provide the best sample purity and structural formula confirmation available for the broad range of compounds in the collection. This database of spectra affords access to the spectra of compounds having desired functional groups and which can be used to establish an identity through empirical comparison. The Sadtler database includes spectra of most simple aliphatic, aromatic, alicyclic and heterocyclic compounds, and also numerous complex materials. Numerous series of homologous compounds, ranging from the very simple to the very complex, which allow spectroscopic studies of trends involving homologs, are also included. The Standards Database is also very useful for the establishment of complex chemical classes of undocumented commercial compounds with similar structures. The molecular structure symbol signifies the molecular structures associated with the database. The structures are available for viewing and substructure searching by special search software.

Apart from the Sadtler database mentioned above, other IR databases for pure organic compounds are also offered (see Table 3). Additionally, a number of dedicated computer collections of IR spectra have been developed, e.g. IR databases for polymers and related compounds, industrial compounds, forensic science, environmental applications and inorganic and organometallic compounds (see Table 3, http://www.bio-rad.com/620859.html). Apart from the above-mentioned computer IR libraries, there are also IR databases provided by producers of
IR spectrometers, e.g. a digitized version of *The Aldrich Library of FTIR Spectra* (over 10 600 spectra), and *The Sigma Library of FTIR Spectra* (over 10 400 spectra of biochemicals) as available exclusively from Nicolet Instruments GmbH, or *Bruker FTIR Libraries* (over 13 400 FTIR spectra) offered by Bruker Analytische Messtechnik GmbH. The next step in the development of SDBs was to create multispectral databases. Most of them include libraries of IR spectra (see Table 4). The experience gathered during IR bases development helped in creating spectral bases for other spectral techniques.

The content of a given multimethod SDB is usually presented as a list of individual catalogs (IR, MS, UV, etc.) and numbers of spectra related to them. The information about the numeric size of the collections in Table 4 is approximate, and it can differ from current numbers, as the databases are being continuously supplemented and transmitted between various scientific centers which include the new databases in their own collections.

### 3 STANDARDS IN INFRARED DATABASES

A very important matter for producers of IR databases (printed and computer collections) is to ensure high quality of the IR spectra. It is also important to define one unified data format for computer collections in order to assure accurate transportation of scientific data between different computer systems and software packages. Accurate transportation of data is an essential element of modern integrated laboratory work. The problem in the quality control of IR SDBs is connected with four main areas: sample preparation, data handling, spectrometer performance and data presentation. With regard to the spectra in an IR collection, attention should be paid to the manner in which a given compound is prepared for an examination. The sample preparation procedures should result in obtaining a reproducible spectrum. The data handling of an IR spectrum downloaded by a computer needs to be controlled by an experienced person in order to avoid any loss of spectral quality and the introduction of any artifacts into the spectrum. Spectrometers used for the registration of reference spectra should be calibrated by standard samples. These three above-mentioned areas determine the quality of reference spectra. All guidelines for the collection of reference IR spectra are formulated by spectroscopic centers. For example, the Coblentz Specifications for IR Reference Spectra of Materials in the Vapor Phase above Ambient Temperature defines the best realistically obtainable spectra as “reference spectra obtained on high-quality commercial instruments operated at maximum efficiency under conditions consistent with acceptable laboratory practice”. Their precise criteria for sample preparation, spectrometer working parameters and spectrum hard copy (e.g. range of spectrum registration, resolution, noise, baseline, recording continuous with no gaps in wavenumber, purged or evacuated spectrometer, linear abscissa in wavenumber, linear ordinate in absorbance, accuracy with sharp bands readable to 3 cm⁻¹).

In addition to sample and spectra registration conditions, the guidelines for collections of spectra elaborated by expert committees for the submission of spectra to the Spectrendatenbanken-Verbundsystem (Germany) also accept the Joint Committee on Atomic and Molecular
Physical Data Exchange (JCAMP-DX) transfer format of spectral data presentation. McDonald and Wilks are the authors of the first JCAMP-DX standard for IR spectroscopy.\(^{(51)}\) The JCAMP-DX is a standard format for IR, UV/VIS, NMR and mass spectra, whereas the Joint Committee on Atomic and Molecular Physical Chemical Structure (JCAMP-CS) format has been proposed for chemical structure coding.\(^{(52)}\) The JCAMP-CS format provides definition for exchanging information on compounds and stereochemistry, and also on the two-dimensional (2D) and three-dimensional (3D) atom coordinates of chemical structures. Where possible, care was taken to make the conversion to other formats in use for representing chemical structures as simple as possible.

The JCAMP-DX format is an answer for those chemists who need a standard file format for the exchange of IR and other kinds of spectra between numerous vendor data systems which nowadays use various proprietary file formats. Unification will enable spectra to be transferred between different spectrometers from their own and other laboratories. The usefulness of the JCAMP data exchange formats has been recognized and accepted by such organizations as the International Union of Pure and Applied Chemistry Committee on Printed and Electronic Publications (IUPAC-CPEP) and ASTM (http://lolita.colorado.edu/faq). This leading standard is also used in SpecInfo SDBs. The implementation of the JCAMP standard as a transport format for IR spectra has been a great step forward in the direction of inter-laboratory communication. However, the international organization of structural and spectral data storage and archiving has been a serious problem. Nowadays, software utility programs permit the conversion of different formats to the one which would be accepted by a given system. For example, the following formats (in addition to the JCAMP) are currently used in each of the software listed:

- ACD/IR Manager: GRAMS, ASCII (http://www.acdlabs.co.uk/products/ir/ir_mg.shtml).

The open and flexible nature of the JCAMP standard and its easy electronic transmission not only on a PC but also in the Scientific and Technical Information Network (STN) International Network are the reasons why this standard will most probably become the most commonly used standard also by SDBs producers and instrument manufacturers.

According to various literature sources, parallel development of printed and computer IR databases can be observed. Owing to the low technological level of spectrometers, the first collections of IR spectra were often of poor quality. Contemporary IR SDBs contain spectra of a considerably higher quality owing to the advent of high-resolution spectrometers and proper sample preparation (according to the standards required).

In addition to large SDBs containing data on different chemical compounds, many collections dedicated to specialized groups of compounds are offered.

Recently, a new type of printed catalog of spectra has appeared on the market. The traditional form of a book is supplemented by a diskette containing peak tables in a digital format, allowing the reader to search for unknowns\(^{(19)}\) (http://www.elsevier.nl/locate/isbn/0444826203).

As far as computer databases are concerned, many efforts are aimed at the unification of spectral and chemical structure codes, which will assist in the easy exchange of information between various scientific centers. IUPAC has additionally published a very positive opinion about the JCAMP format which makes it very probable that this format will be broadly used in the future.

4 STRUCTURE OF INFRARED DATABASES

In this section, some examples of the computer IR database structure is discussed. Since the late 1960s, various computer programs to automate the collection and processing of IR spectra have resulted in different forms of digital representation of spectral data, from the first binary code form\(^{(53)}\) to the latest fully discrete form, e.g. OPUS software system (Bruker),\(^{(54)}\) SpecInfo 3.2–Input Editor (http://cds3.dl.ac.uk/specinfo/ug_input.html) and Sadtler–IR SearchMaster (http://www.sadtlersuite.com/spec.html).

4.1 Information Stored in Spectral Databases

IR databases usually consist of the following data:

- **Compound identification database (CDB).** Each record of the file contains the structural and alphanumeric information about a compound, such as systematic and trivial name, chemical formula, molecular weight, CAS registry number, bibliographic data and selected physicochemical parameters (density, refractive index, dipole moment, melting and boiling point, dielectric constant, etc.). Each of these data and their combinations can be used in searching a certain database in order to find all the information about a compound. Some of the input data (e.g. CAS registry
number, molecular structure) enable one to select the compound unequivocally; others (e.g. molecular formula, molecular weight) provide a list of substances fulfilling the introduced search parameters.

- **SDB.** In this database, separate information about the conditions of a spectrum preparation (instrument, temperature, sample preparation, solvent, frequency region, concentration, cell thickness, optical materials of cell, purity, vertical axis, horizontal axis, etc.) is stored in addition to details about the spectrum itself. In principle, each record contains spectral band parameters, a spectrum in a discrete form and usually also a quality index (QI). The value of QI depends on compound purity, the method of sample preparation, the quality of the spectrometer used, etc.

The above data may be grouped in two separate files (CDB and SDB), but usually the structure of a database is much more complex, i.e. the database contains several files that are related to each other by cross-references.

The information about a structure may be input into a database either in an alphanumerical form (such as list of atoms and bonds and connectivity tables) or in a graphic form. An example of an alphanumerical form is the Wiswesser Line Notation (WLN) used in some Sadtler databases (http://www.bio-rad.com/629418.html) or the JCAMP-CS format accepted for chemical structure coding in the SpecInfo system (http://lolita.colorado.edu/faq).

The graphic program for a structure presentation offers easy molecule construction and provides a full range of structure input methods to be used by a chemist. Chemists can easily draw any structure using a mouse and the program’s interactive sketch function (see Figure 1). Usually when drawing carbon, hydrogen atoms are automatically labeled. The introduced structure is coded and changed to a canonical form. This step is necessary because several different pictures of the same structure exist; the canonical form assigns them all the same code, in which the structure is stored in an SDB. Structural information is the most important of the CDB data as it starts the creation of a record for a given compound. Other CDB information can be input optionally.

### 4.2 Spectrum Representation and Spectral Database Organization

Many systems for archiving collections of spectra on a hard disk (documentary function) have been developed. They give access to information about the structure, spectra and physicochemical parameters of organic compounds, stored in an SDB (information function).

The basis for many computer collections was the ASTM catalog, in which every IR spectrum is presented in a binary (0,1) code generated in the following way: the whole range of a spectrum registration was divided into 0.1 µm intervals; if there was an absorption band in an interval, the interval was given the value 1 and the lack of a band was coded with 0. The virtues of the binary coding form are that it can be stored in a small section of a computer memory (each figure of the code is stored in one bit of memory), and it gives the possibility of using fast algorithms of spectral comparison. The disadvantage of this method is the lack of information about real absorption band parameters (location, intensity and shape).

The development of various computer systems initiated remarkable progress in the creation of molecular spectral computer databases. It was possible to store more information about a spectrum in the databases, which led to changes in the type of data to be stored. The following types of data would be stored:

1. data on the number and location of bands in each spectral coding interval;
2. data on the location of all the bands in a spectrum;
3. data on the location and intensity of chosen absorption bands;
4. data on the location, intensity and factors defining the shape of bands in a spectrum.

None of the mentioned spectrum coding methods would permit the reproduction of a graphic picture of a spectrum. Completion of the already existing spectral data with factors defining shapes of spectra enables one to calculate their curves and finally to display a given spectrum on a monitor screen. Hence the user of the system can compare the analyte spectrum and a spectrum found in the database. The shape of an absorption band can be reproduced by means of a factor called the half band-width and an approximating function (in the most general
case it is a sum/product of Gaussian and Lorentzian functions. Other additional parameters can be directional factors of lines approximating absorption band shapes.

Nowadays, the most commonly used method of spectral coding is via the intensity values of spectral curve points with a constant step of discretization. This method demands a substantial memory for the database. A discrete spectrum code is a set of intensity values coded for a constant step of changes for the horizontal axis. In the database, only the information about the values of the intensity of points will be stored.

The possibility of coding whole spectra in a discrete form in a database appeared first in the late 1970s, together with disseminating magnetic carriers of a large capacity and with the possibility of fast access to the stored data (magnetic disks). Additionally, providing spectrophotometers with computers permitted spectrum archiving in real time (on-line), simultaneously with the analysis being conducted (see Figure 2). Usually, each spectrometer is connected only with its own PC computer, but in some laboratories spectrometers are linked together in the LIMS network, which facilitates the creation of a multispectral data bank.

The generation of a molecular spectral library is carried out as shown in Figure 3. Nowadays, the source data are usually transmitted to a computer directly from an analytical instrument (the on-line method). In exceptional cases, the computer databases must be updated by spectra recorded only in an analog form (such spectra were registered by old types of spectrometers, or the data were taken from the literature), and then a digitizer must be used (the off-line method). The spectra stored in a database are supplemented with additional information about their discretization process. They are also transformed according to the format of given library data. All these spectral data (Figure 3) are compatible with any database management program. Most computer systems demand input data prepared in the JCAMP-DX format to be able to build any IR database. A description of the JCAMP file structure can be found on the Internet under http://members.aol.com/rmcdjcamp/xydatst.txt.

An example of the input IR spectral data is presented in Table 5. The format of the data coded in each line is specifically defined. The JCAMP-DX format accepts three values for step discretization of an IR spectrum (e.g. #\text{DELTAX} = 1.0, 0.5 or 2.0 cm\(^{-1}\)). The step of spectrum discretization is a very important parameter in spectrum representation. To choose the optimal step of discretization, the authors of databases take the purpose of the creation of the set of spectra into consideration. If a database is to be a set of references and spectra are to be processed, this step must be smaller (0.5 or 1.0 cm\(^{-1}\)); it can be bigger when a set is created only to display an image of a spectrum on the screen, or when only information on whether the database contains a given spectrum is needed. Although the discretization step is a very important parameter in evaluating the quality of spectra stored in a computer database, only few authors publish any information about the size of the step, i.e. the resolution for data exchange files. Such information can be found, for example, in the manuals on the Sadtlter databases or on the SpecInfo system.

The use of a spectrum in a fully discrete form is often difficult for LS algorithms, e.g. for the structure identification of an unknown compound. Therefore, in some databases for fast searching, apart from spectra in a discrete form, tables of absorption band parameters calculated from spectra (location, intensity, etc.) are also stored. If a discrete spectrum form is also stored in a computer mass memory, it enables one to display a real spectral curve on a monitor screen. In this case, the optimal number of discretization points depends on the resolution of the monitor (on the number of pixels).
Calculating the values of absorption band parameters is one of the most difficult issues in numerical analysis owing to the complicated character of molecular spectra, which consist of many overlapping absorption bands.

In the 1970s and early 1980s, the problems of the mathematical elaboration of spectral curves were widely discussed in the literature\(^{56,62–65}\) connected with problems of structural identification. Many different solutions and detailed numerical algorithms were presented, the most important of which seems to be the algorithm created by Jones et al.\(^{56,64,65}\). Their numerical algorithm (for calculating the values of absorption band parameters) considers eight basic operations of mathematical spectra elaboration, namely:

- numerical spectrum transformation;
- scale calibration;
- scale correction and transformation;
- numerical filtration;
- deconvolution;
- recognition of overlapping bands;
- localization of isolated and overlapped bands;
- calculation of real parameters of spectral absorption bands.

Commercial software [e.g. PeakFit (http://www.spss.com/software/science/peakfit), STATISTICA (http://www.statsoftinc.com), Galactic GRAMS/386,\(^{40}\) OMNIC FTIR\(^{40}\)] works with the above numerical operations for spectrum curve processing.

The software managing commercial SDBs provides access to information included in the databases in order to enable one to use it, but any changes to the information are impossible, as the databases are protected against any interference. Nevertheless, the user can additionally create his or her own database, e.g. by on-line methods, when the spectrometer is directly connected to the computer. Thus, the user has two SDBs available: the commercial one (only for searching) and a personal library. The user has direct access to the user-defined database(s), and can take one of the following actions: add new data, delete data, correct data and delete the whole database. Hence the spectroscopist has a tool for the documentation of his or her work and for the identification of compounds which are present in his or her personal SDB. The commercial databases are enlarged by successive upgrades on a PC or by access to a network data bank, disseminated for users.

As the IR curve depends strongly on the method of sample preparation (e.g. KBr pellet, liquid film, solution in a given solvent, vapor), the storage of several IR spectra for one compound is useful when an SDB is applied to studies concerning the influence of spectrum registration conditions (temperature, pressure, concentration, etc.) on band location and band intensity. In this case, a single structure of a compound is stored and is connected by the cross-references with all its spectra. Special procedures enable one to compare various spectra in order to observe any differences between them. Such a solution is applied in the SCANNET system, with which one can gather five different IR spectra (of one compound) obtained under different conditions. The system also enables observation of the phenomena\(^{61}\) that cause changes in the spectral band shape and also the disappearance and/or appearance of the bands. The investigation of the phase transition of dichloromethyl tert-butyl ketone is shown in Figures 4–6.
Figure 4 IR spectrum of the crystalline form of dichloromethyl tert-butyl ketone.

Figure 5 IR spectrum of the liquid form of dichloromethyl tert-butyl ketone.

Figure 6 Overlapping and differential IR spectra of dichloromethyl tert-butyl ketone.
INFRARED SPECTROSCOPY

Figure 7 IR spectra of allyl phenyl ether (bottom) and o-allylphenol (top).

Figure 8 Overlapping and differential IR spectra of allyl phenyl ether and o-allylphenol.

The IR spectrum of the crystalline form of the substance is presented in Figure 4 and Figure 5 presents part of the IR spectrum of the liquid form. It can be seen from the overlapping spectra and from the differential curve (see Figure 6) that the spectrum of the substance in the liquid phase contains only one band at 797 cm\(^{-1}\) instead of two bands at 799 and 778 cm\(^{-1}\), characteristic of the crystal phase.

The storage of different spectra for one compound can be used for studies of the Claisen rearrangement of allyl phenyl ether to o-allylphenol is shown in Figures 7 and 8. On these figures one can observe a strong band at 3430 cm\(^{-1}\) (due to the stretching of the O–H bond of the hydroxyl group) in the product spectrum, which is absent in the substrate spectrum.

5 RECOGNITION OF CHEMICAL COMPOUND STRUCTURE

Many attempts have been made in recent years to make the structure elucidation process faster and more reliable by using computers. All the methods presented below (LS algorithms, correlation tables method and neural networks) use IR databases.

The structure of these databases differs for each of these methods. The LS method works on large (tens of thousands) collections of spectra and enables one to find in a database a set of compounds identical with or similar to the analyte compound.\(^{(68)}\) In the case of the other two methods, a database is used on a level of generating the identification system. When the correlation tables method is applied, the IR spectral library
(containing from several hundred to several thousand spectra) is used to generate a knowledge base consisting of spectra–structure correlations (presented as tables, interpretation rules or decision trees). The generated knowledge base, together with the inference engine, forms an expert system for structural fragments recognition. The last method uses one specially transformed IR database to learn (to train) how to recognize chosen structural fragments. Once a network has been trained, it is able to identify the fragments without using the IR spectral library.

5.1 Library Search Algorithm

The identification of a chemical compound structure based on the application of an IR library consists in looking for the identity or similarity between the spectrum of an unknown substance and one or more spectra from the standard collection. The reasoning is based on the logic Clerc cycle assuming that the identity or similarity of the examined and reference substances spectra proves the identity or similarity of their structure. Obviously, some assumptions which would enable one to realize an inference process must be fulfilled (the same method of sample preparation, the same coordinates, similar spectrometer settings, etc.). The control of the data stored in a database is particularly important, as the shape of an IR band is strongly dependent on the mentioned parameters. Therefore, the algorithm comparing the spectra should be preceded by the control of spectrum registration conditions. This algorithm LS algorithm is based on a known paradigm of artificial intelligence – “describe-and-compare”. The LS algorithm imitates the reasoning of a chemist, who elucidates the structure of a chemical substance by comparing its IR spectrum with successive spectra of known compounds stored in a database. In the case of an automatic (computer) realization of the LS algorithm, not the whole spectral curves are being compared, but only some selected spectral features, so the algorithm for calculating the measure of the identity/similarity of the features must be defined.

It is assumed that for spectral features being compared, one of the following relations exists:

- spectral feature are identical
- spectral feature are similar
- spectral feature are different
- spectral feature do not resemble

These relations are realized according to detailed solutions accepted by a given author. Generally, the LS algorithm is realized in the following steps:

1. the conversion of an unknown compound spectrum into a digital form, exactly the same as that used for reference spectra in a database;
2. the sequential comparison of the numerical representation of an unknown spectrum (of an analyzed compound) with successive spectra in a database;
3. the output of information about the results of searching the database, i.e. a list of spectra identical with or similar to the analyte spectrum, on the basis of a predefined criterion for spectral similarity (strictly, similarity of numerical representations).

The list of these spectra is usually sorted according to decreasing values of their fitting factor, which is a measure of spectral similarity. A value of the fitting factor of 1 refers to complete identity of the spectra being compared, whereas a value of 0 implies a lack of any similarity between them. A chemist is the one to take the final decision about which of the structures proposed by the program is that sought. The LS method of the identification of unknown compounds from their IR spectra has been widely applied for practical purposes. Now, every FTIR instrument has functions for database searches on its minicomputer. However, the success of the database search method depends on the size of the database. That is, in order to identify an unknown spectrum, its precise (or highly similar) reference must be included in the database. However, when the size of the database becomes larger, the search will take longer, which is especially critical in the case of systems on PCs. For this reason, with neural network application a new technique for faster searching of IR databases was elaborated.

An example of a real procedure for the elucidation of an unknown compound structure aided by a LS method is shown in Table 6 and Figures 10 and 11. The unknown compound was identified by means of the IR spectrum. The IR spectrum in a discrete form was the input data; the spectral bands selected for searching are presented in Table 5. After searching the IR database, a list of substances having IR spectra identical with or similar to the input spectrum was obtained. The list contains one compound with a fitting factor of 1.0 (1-pentanol) and...

Figure 11 Overlapping IR spectra: (1) unknown spectrum; (2) 1-hexanol.

others with fitting factors <1.0. Overlapping IR spectra are presented in Figures 10 and 11. Here, the unknown compound and 1-pentanol are identical, whereas the spectrum of 1-hexanol differs slightly from the unknown spectrum (fitting factor 0.94). The analyte compound therefore has the structure of 1-pentanol.

The weakness of the LS approach is related to the necessity for a powerful computing system and a large database. Also, even a large database may not contain identical or very similar reference spectra with respect to the sample spectrum. The LS method can thus solve the problem of structure identification when the database contains a spectrum identical with (or very similar to) the sample spectrum. Otherwise, to elucidate the structure of an unknown compound it is necessary to use methods that permit the recognition of structural fragments present in the molecule of the analyte substance. The IR library can also be applied to discover spectrum–structure correlations.

5.2 Discovering Spectrum–Structure Correlations from Infrared Databases

A different approach in spectral interpretation is based on the determination of functional groups which may be present in an unknown compound. Several computer programs have been written in order to mimic the human process of interpreting an IR spectrum of an unknown compound. These programs\(^{76,77}\) use correlation tables (a list of structural fragments and their spectral characteristic parameters) which can form a knowledge database or be an integral part of the program. Usually, these parameters are taken from literature\(^{73–88}\) but they
can also be generated from a computer library of IR spectra.\(^{(77,86,89,90)}\) The first approach of using information from the literature was applied in the X-PERT system,\(^{(88)}\) which contains a set of molecular fragment libraries and the spectral features of fragments (for IR spectroscopy, the ranges of characteristic frequencies, intensities and band half-widths). For example, the \(\text{CH}_2=\text{CH}^–\) group is described by four diagnostic intervals: 880–900, 1395–1440, 1640–1655 and 3010–3120 cm\(^{-1}\). The second approach\(^{(86,87)}\) consists in generating spectra–structure correlations from a computer library of IR spectra, which is an automated knowledge acquisition from an IR database. The acquisition of spectral information is done in order to create rules allowing the identification of molecular fragments of an unknown compound from its IR spectrum. The process of searching for spectrum–structure correlations can be realized by computer-simulated neural networks,\(^{(89,90)}\) by application of a statistical algorithm\(^{(77)}\) or by the combination of a statistical algorithm with an algorithm related to the set theory.\(^{(86)}\) The statistical algorithm (see Figure 12) splits the database into subsets with and without a given substructure. Next, it divides the IR spectral range into intervals, and counts the number of spectral features (absorption bands) present in the spectral intervals separately for each subset. Then, the normalized histograms (confidence factor (CF) for each interval) for both subsets are calculated. The difference between these histograms (interpreted as being the effect of only some characteristic spectral features) is converted into correlation tables. After their evaluation by a chemist, the correlations are automatically transformed into rules for substructure identification, a set of rules form a knowledge base being a part of the expert system for structure elucidation.

The basic lemma of the algorithm relying on the set theory applied by Ehreintreich et al.\(^{(86)}\) is that every compound containing a substructure \(S\) must contain at least one absorption band in every characteristic interval described by a subset of the spectroscopic features: band location, intensity or half-width. This lemma is necessary with respect to strong logical conclusions but it is not fully justified with regard to excitation rules in IR spectroscopy (e.g. problem of center of symmetry). The core of the algorithm lies in a search for a large set of intervals as small as possible. The correlation obtained by these two algorithms can be finished manually by comparison with literature data and next transformed into a rule base for interpretation of IR spectra.

The application of this statistical algorithm for the generation of spectral correlations is presented for the amine group (see Figure 13a–c). The histogram has been plotted as a statistical area diagram using location (cm\(^{-1}\)) and CF as coordinates. The rectangular

![Figure 12](image-url)

**Figure 12** Algorithm corresponding to automatic knowledge acquisition from IR database.

height corresponds to the diagnostic power of the spectral interval. From among all the components of the diagnostic vector (see Figure 13a), the components of the maximum value components (CF < 20%) were chosen (see Figure 13b). Next, they were converted into correlation tables of the investigated substructure (see Figure 13c). One can see (see Figure 13b) that for the \(-\text{NH}_2\) substructure three diagnostic regions fulfill these conditions. In the first region four intervals (Nos 1, 2, 4 and 5; yellow) were classed, in the second two intervals (Nos 3 and 7; gray) and in the third one interval (No 6; white).

The result of searching for structure correlations depends strongly on the IR database used in the process of searching. The spectral ranges generated from an IR database containing spectra of various types of chemical compounds are wider than the relevant ranges obtained by using dedicated bases (IR collections of carboxylic acids, hydrocarbons, etc.). The interpretation rules are of the general form

\[\text{IF conditions THEN hypothesis}\]

The **conditions** may be represented by logical expressions:\(^{(77,86,88)}\) \(A \text{ AND } B, A \text{ OR } B,\) where \(A\) and \(B\) are the spectral features. In the **hypothesis** represented by logical expressions \(C \text{ AND } D, C \text{ OR } D,\) symbols \(C\) and \(D\) are the substructures identified by \(A\) and \(B\) spectral features. Thus, the rules can have the form:

\[
\text{IF } A \text{ THEN } C ; \text{ IF } A \text{ AND } B \text{ THEN } C ; \\
\text{IF } A \text{ OR } B \text{ THEN } C \text{ AND } D , \text{ etc.}
\]
INFRARED SPECTROSCOPY

Figure 13 Spectrum–structure correlations generated for −NH₂ substructure.

A standard example of the substructure identification rule is as follows:

where n = number of the bands characteristic of the analyzed substructure.

This type of rule (related to spectral correlations) is then augmented by a set of rules required to control the inference engine, steering the way of reasoning and output of obtained results. The complete knowledge base generated is in the next step compiled and used by the reasoning section of an expert system. During the consultation, the user enters spectral parameters (band locations and intensities) of the spectrum of an unknown compound. The inference engine accessing the knowledge base generates the list of substructures that would possibly constitute building parts of the investigated structure (see Figure 14).

5.3 Neural Networks as Tools for Structure Recognition

Apart from a LS, the use of correlation tables and many different pattern recognition techniques, and also the application of computer-simulated neural networks (abbreviated to neural networks) working on a base of an encoded spectral collection, has been attracting increasing interest in the last few years. The main purpose of this method is to extract structural information from spectral data; however, neural networks have also been used for predicting spectral features (i.e. for simulating spectra) from a chemical structure, and also for the identification of IR spectra, i.e. to find in the IR spectral library a spectrum identical with the analyte (the alternative approach to the LS method).

Neural networks are known to be able to learn and then to recognize patterns, so neural networks constitute a means of pattern classification in which an input pattern (a vector the values of which represent object data) is transformed into an output pattern (a vector the values of which represent the desired classification of the object data). In structure elucidation, the input pattern is a representation of an IR spectrum of an unknown compound and the output pattern is a representation of functional groups (substructures) present or absent in the compound. The transformation is achieved by a propagation equation which combines the input vector with coefficients internal to the network. The coefficients are generated by a process called training or learning.
Starting from random values of the coefficients, output vectors are calculated from a set of input vectors (encoding IR spectra) for which the “right answers” (presence or absence of recognized groups) are known, the right answers being encoded in a target vector. After the calculation, a learning rule uses differences between the output values being obtained and target values to modify the coefficients. As this process is repeated, the coefficients gradually converge to values which transform each input pattern to an output pattern closely conforming to the target. Once a neural network has learned to recognize the given substructures, it can be used for the prediction of the presence or absence of these substructures in an unknown compound from its encoded IR spectrum.

For substructure recognition, the most commonly used approaches are “error-back-propagation” learning methods in multilayer neural networks, and two simple architectures, mono- and multioutputs. Mono-output networks are specialized networks trained to recognize only one particular substructure, whereas multioutput networks are trained to recognize simultaneously several substructures from a single input vector. The hierarchical system of neural networks is half way between one large neural network with many outputs and many mono-output networks. In most work a digitized spectrum was the spectral information used as a network input, so that the number of input elements can vary between approximately 100 and 4000 (for an IR spectrum it is usually about 256 or 512 elements). Another means of spectrum encoding is to divide a spectral range into intervals, assigning each interval to an input unit, and giving for the unit a nonzero value if a band occurs in a frequency interval, or zero otherwise.

An example of the application of neural networks to structure prediction is the work presented by Novič and Zupan. A training set of about 755 IR spectra was selected from the IR database using the Kohonen layer in a neural network. The spectra in the range from 3500 to 550 cm\(^{-1}\) are coded as 512 intensity points, which after Hadamard transformation are reduced to 128 intensity values (1:4 reduction). The structures of compounds included in a training set of spectra were coded as 34-dimensional binary vectors. The ones and zeros correspond to the presence or absence, respectively, of a particular fragment (34 structural fragments were defined and coded; see Table 7). These coded IR spectra and structure vectors corresponding to them were the input data to the neural network. It was assumed that the network after a training process will be able to recognize the presence or absence of these structural fragments in a molecule of an unknown compound from the compound’s IR spectrum. The counterpropagation neural network, i.e. a two-layer network consisting of a Kohonen and an output layer, was used in the training process. The learned (trained) network was tested on a database of 2529 IR spectra (encoded in the same way as the training spectra set) of known substances. The prediction correctness was calculated and evaluated separately for two sets, a set of compounds containing the tested substructure and a set of compounds without this substructure. The evaluation of the neural network’s predictive features was dependent on the number of substructures identified correctly. “Correct identifying” means that a given substructure was recognized in a structure of which it was really a part, and it was not recognized where it did not exist. The highest prediction correctness was for the groups carbonyl (96%), carboxyl (94%) and hydroxyl in alcohol (93%). Poor prediction results of less than 35% were obtained for furan (31%), CBr (30%), thiophene (19%) and CI (0%). It can be concluded that the vibrations caused by these and similar fragments are not significant in the IR region, or their influences on IR spectrum are lost among other (more dominant) spectral features.

Very interesting work concerning the correlation of IR spectra with a molecular structure were presented by Gasteiger’s group. The most important achievement was the successful application to spectrum–structure correlation problems of a novel and original way of coding 3D molecule structures. It is based on equations used in the analysis of the intensity distribution, which can be obtained in electron diffraction experiments. Structure coding and inductive learning algorithms allow one to store the relationship between the 3D structure of a molecule and its IR spectrum in a neural network. The relationship is stored in the weights of a counterpropagation neural network. Such a network is able to simulate an IR spectrum by inputting the coded structure of a molecule. On the other hand, a structural code of a molecule can be predicted by inputting an IR spectrum. As the second step, this structural code can be decoded to obtain Cartesian coordinates of the atoms in the molecule.

A number of authors proved that computer-simulated neural networks provide a practical method for detecting the presence and absence of functional groups on the basis of IR spectral data. Thus, the neural network can be used as a program for structure determination of an unknown chemical compound, and can also cooperate with an expert system for structure elucidation. The combination of a neural network and an expert system can be used in two distinctly different manners. In the first, the network is used in cooperation with an expert system to analyze an unknown compound; in the second, the network is used to help in the creation of rules which the expert system will use. In the first case, the neural network is used directly and simultaneously in connection with the expert system, and the conclusions about the presence

\( a \) \( p_i^a \) = fraction of correct prediction for compounds containing substructure number \( i \) (fraction of recognized substructure).

\( b \) \( p_i^b \) = fraction of false prediction for compounds containing substructure number \( i \) (fraction of unrecognized substructure).

\( c \) \( R_i \) = reliability of substructure recognition, \( R_i = 2(\frac{+p_i - -p_i}{1 + +p_i - -p_i}) \).

(or absence) of a substructure are entered into a database of facts which are then used by the expert system. In the second case, the neural network can be used indirectly, providing information (extracted from the coefficients of the network) which enable one to fix the correlations between the substructures and their spectral features. The correlations can next be taken into consideration when writing the rules for the expert system.

6 MULTIMETHOD SPECTRAL DATABASES

The computerized processing of spectral information has become a routine procedure for many laboratories in the last few years. The use of artificial intelligence to combine spectral information obtained by various spectral techniques is essential for the determination of a chemical structure. It is a more efficient solution than the application of only one spectral method because the results obtained by using different spectral techniques will be more accurate than when only one technique is used.

Multimethod SDBs (also called spectral data banks) contain some general information on chemical compounds (see section 4.1, definition of CDB) and/or on bibliographic references, as also monomethod databases obtained by use of various spectral techniques (see Table 4).

In this section, only spectral data banks containing also IR databases will be discussed. Each of the databases uses
a number of special programs, generally specific to a single spectroscopic method, for spectral data analysis and interpretation. The identification of a compound structure consists in the analysis of the results acquired from searching within separate databases, and the results can be combined to increase both scope and accuracy. This function can be fulfilled by the main managing program summing the results of separate database searches. Usually, these results are shown as a list of compounds having bands identical with or similar to those for the examined compound. Finally, a global list including compounds present in all individual lists is created. Multimethod analysis provides more reliable results (higher SI) than the application of only one spectroscopic method. For all the compounds in a global list, all the spectra must comply with the requirements of similarity, i.e.

\[
\text{global list} = (\text{IR list}) \text{ and } (\text{H-NMR list}) \text{ and } (\text{MS list})
\]

Another procedure enables the user to select a different way of creating the global list, e.g.

\[
\text{global list} = (\text{IR list}) \text{ and } [(\text{Raman list}) \text{ or } (\text{UV/VIS list})]
\]

The chemist can choose “and/or” logical symbols and modify the search method according to his or her knowledge of the problem. If it is not possible to create a common results list (structures of a high SI), a list of substructures apparently occurring in the examined compound is built. Next, the probable structures and their spectra are generated. The calculated and experimental spectra are then compared with each other to choose the right structure from the candidate structures set.

Multimethod SDBs can be built by linking some spectral libraries with the already existing databases. The libraries can be obtained from industrial or university laboratories and also from various publications. Before being introduced into the bank, these data are carefully checked and transformed into a standard form. A multimethod system built in such a way includes databases which are not directly linked with each other. As a result of such system searching, separate structure lists are obtained. For example, Bio-Rad offers two Sadtler PC software products [i.e. IR Search Master version 3.0 and NMR Search Master version 3.1 (www.bio-rad.com/610441.html)] for searching various collections of IR and 13C-NMR spectra.

One of the most important multimethod integrated SDBs is SpecInfo, which was developed by BASF for in-house use. Actually, the SpecInfo system is available both as an in-house system through Chemical Concepts (www.dl.ac.uk:800/CDS/spectro.html) and for on-line use through the STN International (www.wiley-vch.de/cc/si_onl.html). The SpecInfo databases are updated thanks to the cooperation between the two experienced partner institutions [the Institute for Spectrochemistry and Applied Spectroscopy in Dortmund (IR and NMR spectra) and the Max-Planck-Institut für Kohlenforschung in Mülheim (mass spectra)].

The SpecInfo on-line version provides information on chemical structures together with spectral information. It permits more than simple similarity searches and provides several run packages to assist users in important structure elucidation matters. For IR spectra, SpecInfo offers various search modes which may be performed using either the complete spectrum or just some of its defined ranges. Recent enhancements include cross-links to the CAS registry and the Beilstein Database.

Another example of multimethod SDBs, with entries connected through the structures of chemical compounds, which allows simultaneous access to all kinds of spectra stored for a given compound, is the Sadtler system. A user-friendly option gives the possibility of observing all the available spectra on a common screen. This option was adapted from, among others, the Sadtler User Library, the Main Manager program of which makes possible full viewing, plotting and coordination of IR and UV spectra, chemical structures, physical properties and bar charts for NMR and mass spectra, all in a sample spreadsheet format. Another example of this kind of system is SCANNET, which assumes that within the identification methodology the results of a given randomly selected spectral interpretation (IR, MS, etc.) should influence the process of subsequent spectral interpretation through the cascade of facts logic.

This notion stands for the integrated interpretation of various molecular spectra of a given compound by the logical conjunction of intermediate analyses. The successive steps of the algorithm (see Figure 15) are as follows:

1. selection of a spectral method (i.e. SDB);
2. input of selected absorption band parameters and (if there is access) input of a spectrum in a discrete form;
3. searching the database for input absorption bands; the structure recognition of an unknown substance is made by comparing the input spectrum with another.

</table>

The identification is realized in three subsequent cycles. When the investigated structure does not exist in a database, the chosen spectra have a SI smaller than 1.0. If the process of searching an SDB gives a list of similar spectra, the result of the investigation is a hypothesis about a possible structural similarity between

(a) new spectral methods or (b) other spectral band parameters.

An example of the use of the cascade of facts logic is a structure recognition of an unknown compound led only on a basis of IR, mass and Raman spectra. The identification is realized in three subsequent cycles. When the investigated structure does not exist in a database, the chosen spectra have a SI smaller than 1.0 (see Table 8). If the process of searching an SDB gives a list of similar spectra, the result of the investigation is a hypothesis about a possible structural similarity between successive reference spectra of standard compounds (chemical compounds of a known chemical structure) stored in a SDB; the end of a structure elucidation (see Figure 15, STOP command), if the output list satisfies the chemist; he or she can reinterpret the results by presenting the overlapping spectra on one screen and deciding to repeat the search process, choosing...
the structure of the unknown compound and one or several structures from the obtained list of similar spectra, depending on the SI. The result of the process of IR, mass and Raman spectra interpretation, three proposed structures, is presented in Table 8 and Figure 16. In the first cycle of recognition, the identification was carried out using only the IR spectrum, as a result of which 25 compounds (column c, global list) were found similar to the examined one. In the second cycle, the MS database was searched and 20 compounds (column c) were found similar to the analyzed substance. The comparison of the two lists (IR and MS) reduced the number of candidate compounds to seven substances (column d, global list). In the third cycle, similar analyses were performed for Raman Spectroscopy. From the Raman database 53 spectra were selected as similar to the Raman spectra of the unknown compound. Comparison of the Raman list with the IR and MS global lists reduced the number of candidate compounds to three. All spectra of the selected compounds (Figure 16) are similar to the analyzed compound’s spectra, with n-butylbenzene being identified as the most similar one (SI = 0.93). As shown, the compound was univocally identified. All spectra of the compound stored in the system database can be seen on one screen (see Figure 17).

ACKNOWLEDGMENTS

The authors are especially grateful to Professor D. Cabrol-Bass (Nice–Sophia Antipolis University, Nice, France), Professor M.E. Elyashberg (All-Russia Research Institute of Organic Synthesis, Moscow, Russia), Professor L.A. Gribov (V.I. Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, Moscow, Russia), Professor Z.H. Hippe (Rzeszów University of Technology, Rzeszów, Poland) and Professor J. Zupan and Dr M. Novič (Institute of Chemistry, Ljubljana, Slovenia) for the reprints of their papers, which were a great help in our work on this article.

We express special acknowledgment to Professor J.T. Clerc (University of Berne, Swiss Federal Institute of Technology, Zurich, Switzerland) for his great interest, encouragement and help in our work.

We appreciate the support of the State Committee for Scientific Research (Warsaw) with Grants 8 8308 92 03 and 8 T11C 004 09 to assist our research in the field of IR SDBs.

Sum frequency generation (SFG) vibrational spectroscopy is a nonlinear optical vibrational spectroscopy, which has been shown to have submonolayer surface sensitivity. It has been developed into a powerful technique to investigate molecular structures of surfaces and interfaces. This paper introduces the technique of SFG spectroscopy and discusses several important SFG applications. One of the most important advantages of SFG over many traditional surface-sensitive techniques is that SFG does not require high vacuum to operate. Therefore, it can be applied to investigate liquid surfaces and interfaces, as well as interfacial biological molecules in biologically relevant environments. The SFG applications discussed in this article are (i) simple liquid surfaces and interfaces, (ii) polymer surfaces in water and polymer/silane interfaces, and (iii) interfacial structures of peptides and proteins.

1 INTRODUCTION

The chemistry at surfaces and interfaces is important for everything from high-tech industry to everyday life. The usefulness of many common items is determined by surface properties, for example contact lenses must remain wetted, while raincoats are designed to be nonwetting. The chemistry of surfaces has been tailored for many applications including antibiofouling surfaces for marine vessels, high-temperature-resistant surfaces for space shuttles, and heterogeneous catalysts.

Surface chemistry is also important in biology. The human body contains many different surfaces that are vital to our well-being. Surface chemistry is responsible for protein interactions with cell surfaces, hormone-receptor interactions, and lung function for example. To understand functions of biological molecules at interfaces inside our bodies and to prepare surfaces of advanced materials with desired properties, it is essential to understand the molecular-level structures of these surfaces in situ.

Excellent research on many surfaces and interfaces has been performed using a wide variety of analytical techniques.(1,2) However, many challenges still exist in the field of surface analytical chemistry. Many of the standard surface analytical chemistry techniques such as X-ray photo electron spectroscopy (XPS), secondary ion mass spectrometry (SIMS), scanning electron microscopy (SEM), and scanning tunneling microscopy (STM) require high vacuum to operate. These techniques are powerful surface-sensitive analytical tools, but it is difficult to apply them to the study of liquid surfaces/interfaces or buried solid interfaces.

Various techniques have been researched to study surface structures in liquid environments. For example, freeze-drying XPS has been developed to study polymer surface restructuring in water,(3) under the assumption that the freeze-drying process would not alter the polymer surface structure and thus the polymer surface will have the same structure as that in water. Such a method only provides surface elemental analysis rather than surface functional groups.

Contact angle measurements are easier to perform and can be used to study surface hydrophobicity.(4,5) Many surfaces (e.g. polymer surfaces) restructure when they are exposed to water, but contact angle measurements cannot provide a molecular-level picture of how the polymer surfaces change. These changes should have a molecular origin; that is, they are thought to be caused by the migration or reorientation of groups, segments, or side chains relative to the aqueous phase to minimize the interfacial free energy. Atomic force microscopy (AFM) has been used to study surface morphologies and surface properties (e.g. friction or adhesion) of many materials in a variety of chemical environments including aqueous solutions with excellent spatial resolution, but AFM cannot probe surface chemical structures.(6,7) Different theoretical models have been developed to simulate the details of the surface restructuring in water for decades, but the models need to be verified by molecular-level experiments.

Those techniques that can provide molecular-level structural information and do not require high vacuum, such as attenuated total reflection Fourier transform
infrared (ATR-FTIR) spectroscopy and surface enhanced Raman scattering (SERS), are less surface specific than SFG. ATR-FTIR detects signals from many layers, rather than the topmost layer on the surface. In addition, SERS requires special substrates to enhance the signal, which may not be ideal to study different surfaces and interfaces like biosurfaces.

SFG vibrational spectroscopy has been developed into a powerful analytical technique to examine molecular structures of surfaces and buried interfaces.\(^{8-15}\) SFG is a second-order nonlinear optical spectroscopy, which can provide vibrational spectra of a surface or an interface with submonolayer sensitivity.\(^{10-15}\) It does not require a high vacuum to operate; therefore it can be used to probe various surfaces/interfaces including liquid surfaces under ambient conditions. It can follow molecular-level chemical structural changes of surfaces and buried interfaces in situ and in real time. SFG spectrometers are more complicated compared to traditional Fourier transform infrared spectroscopy (FTIR) or Raman systems. Owing to the fast development of advanced lasers and nonlinear optical research, SFG equipment is becoming more mature, stable, and user-friendly. SFG research has grown substantially in recent years and numerous academic and industrial labs have been equipped with SFG systems (see Theory of Infrared Spectroscopy; Infrared Spectroscopy: Introduction; Raman Spectroscopy: Introduction; Fourier Transform Raman Instrumentation: Raman Microscopy and Imaging: Raman Scattering, Fundamentals; Ultrafast Laser Technology and Spectroscopy).

The aim of this article is to introduce the SFG technique and its applications to scientists in other research fields and to beginners in SFG studies who are not very familiar with this technique. Thus, only a brief introduction instead of an in-depth discussion of the SFG theory and technique is presented here. Many quantitative SFG data analysis methods and SFG technical details are omitted. Instead of thoroughly covering all the excellent SFG results from the many SFG research labs on a wide range of different research subjects, this article presents only applications of SFG with respect to several particular research directions to deliver a general idea to the readers about what SFG can examine and why the results obtained from such SFG studies are important and unique. More details can be found in the numerous excellent SFG review papers and original research articles.

The article is organized as follows: after this brief introduction, SFG theory and instrumentation are briefly discussed. Then SFG applications in studying liquid surface and interfaces of small molecules, polymer surfaces and interfaces, and interfacial biological molecules such as proteins and peptides, respectively, are presented. As stated, the purpose of this article is to introduce the SFG technique and its applications to the readers who do not know this technique well. It is hoped that this article will promote their interests in exploring the possibility of applying SFG spectroscopy to solve some of the questions in their research areas.

2 SUM FREQUENCY GENERATION THEORY AND INSTRUMENTATION

SFG spectroscopy provides vibrational spectra of molecules. SFG can elucidate surface/interfacial structures at the molecular level for a centrosymmetric material. FTIR and Raman scattering are the most widely used vibrational spectroscopic techniques. An SFG spectrum is similar to an FTIR or Raman spectrum, which plots the signal intensity as a function of infrared (IR) wavenumber, but an SFG spectrum is specifically from the surface functional groups in a centrosymmetric medium.

FTIR and Raman are linear spectroscopic techniques. FTIR is a one-photon process where an IR photon interacts with a molecule, and if its frequency is in resonance with a vibrational mode of the molecule and if the dipole moment changes during the vibration, the photon can be absorbed. A normal Raman process is a scattering process that involves two photons. The incoming photon can gain or lose energy when it interacts with the molecule. The outgoing photon will contain information about how much energy was gained or lost to the molecule, which is dependent on the vibrational energy levels of the molecule. The energy difference between the two photons matches the energy difference between vibrational states of the molecule. A vibrational mode is Raman active if the polarizability changes during the vibration.

As opposed to FTIR and Raman, SFG is a nonlinear process that involves three photons: two incoming photons and one outgoing photon. The outgoing photon is at the sum frequency of the two input photons. Figure 1 shows the energy-level diagrams of the IR, Raman, and SFG processes. Clearly an SFG process is a combination of an IR process and an anti-Stokes Raman scattering. In a typical SFG experiment using a frequency-scanning

![Figure 1](image-url) Energy-level diagram of FTIR (a), Stokes and anti-Stokes Raman scattering (b1 and b2), and SFG (c).
system, two input beams, a frequency-fixed visible light and a frequency-tunable infrared light, shine on a surface/interface (Figure 2) and the sum frequency signal beam is detected. The intensity of the sum frequency signal beam is plotted as a function of the input IR wavenumber. When the frequency of the input infrared beam matches a vibrational resonance of molecules on the surface, the SFG signal is enhanced. Only if a vibrational mode is both IR and Raman active can it be observed in SFG experiments.

Under the electric dipole approximation, SFG signal intensity is proportional to the square of second-order nonlinear susceptibility \( \chi^{(2)} \) of the material under study. This \( \chi^{(2)} \) is a polar tensor, so it will change sign under the inversion operation: \( \chi^{(2)}(r) = -\chi^{(2)}(-r) \). However, for a material with inversion symmetry, nothing will be changed under the inversion operation: \( \chi^{(2)}(r) = \chi^{(2)}(-r) \). Clearly the only possible solution for the above two equations is \( \chi^{(2)} = 0 \). Therefore, for materials with inversion symmetry the SFG process is forbidden. Many bulk materials do have inversion symmetry and thus they do not generate SFG signals. However, inversion symmetry is inherently broken at an interface. Here, \( \chi^{(2)} \) does not need to be zero, and SFG signals can be detected. Owing to this selection rule, SFG is intrinsically surface specific and has been demonstrated to have a submonolayer surface sensitivity. \(^{10-15}\)

As mentioned, ATR-FTIR and SERS have been widely applied to study surfaces. However, the surface sensitivity of ATR-FTIR is limited by the penetration depth of the IR light, which is on the order of hundreds of nanometers to a few micrometers. Thus, its surface sensitivity is not comparable to SFG. SERS requires a metal substrate and thus is not as flexible as SFG, which can be used to study many different kinds of surfaces and interfaces. In addition, SERS does not have the submonolayer sensitivity and surface specificity of SFG.

Two different kinds of SFG systems, either a broadband system or a frequency-scanning system, are typically used to collect SFG spectra.\(^{10}\) A broadband system involves a femtosecond laser, which has a broad frequency spectrum. Therefore, many vibrational modes are excited simultaneously. The signal is typically spectrally spread over a charge-coupled device (CCD) camera and the signals from different vibrational modes are collected simultaneously. Further details have been reported in previous publications and will not be repeated here.\(^{10}\)

The authors’ research group has two frequency-scanning systems.\(^{17}\) Each system is composed of the following components: a picosecond Nd:YAG laser, a harmonic unit with two KD*P crystals, an optical parametric amplification (OPA)/optical parametric amplification (OPA) and difference frequency generation (DFG) system based on Lithium Triborate LiB₃O₅ (LBO) and AgGaS₂ crystals, and a detection system. The green visible input beam (532 nm) for an SFG experiment is generated by frequency doubling the fundamental output pulses of 20 ps pulse from the Nd:YAG laser. The IR beam can be tuned from \( \sim 1000 \) to 4300 cm\(^{-1} \), generated from the OPG/OPA and DFG system. By replacing the AgGaS₂ crystal with a GaSe crystal, this range may be extended down to 650 cm\(^{-1} \). The diameters of both the visible and IR beams at the surface are about 500 µm. The SFG signal from the surface is collected by a gated photomultiplier tube. The pulse energies of the IR and visible beams are around 100 and 200 µJ, respectively, depending on the samples used in the experiment. SFG spectra with different polarization combinations such as sps (s-polarized output, s-polarized visible input, and p-polarized IR input), ppp, and ssp can be used to deduce orientation information of surface functional groups.

SFG spectra are usually collected from optically flat surfaces, as shown in Figure 2. In the past, most SFG studies have focused on the C–H, N–H, or O–H stretching frequency regions because of experimental equipment limitations. Thus, the data analysis for these functional groups has been extensively discussed. Recently, SFG signals in lower frequency regions have been collected and analyzed. In this article, structural information of proteins and peptides at interfaces according to their SFG amide I signals will be extensively discussed.

In addition to identification of various functional groups’ presence on the surface from SFG signals (e.g. from characteristic peak centers), orientation information of such surface functional groups can be deduced from SFG spectra collected in different polarization combinations. Details regarding the orientation analysis of such surface functional groups using SFG have been extensively discussed in many previous publications\(^{18-24}\) and will not be repeated here. The general idea is similar to a polarized FTIR or ATR-FTIR experiment. In a polarized FTIR experiment, when a different s- or p-polarized beam is used, the transition dipole of a vibrational mode of the molecule is projected onto different axes and such projections measured from which the orientation can be deduced. For SFG, the molecular
3 SUM FREQUENCY GENERATION APPLICATIONS

After the demonstration of the feasibility of collecting SFG vibrational spectra from interfacial molecules in 1987 by Shen et al., SFG has been developed into a powerful surface-sensitive analytical technique. It has been widely applied to study many important surfaces and interfaces, including many liquid surfaces and interfaces, which will be discussed in detail in the next section. Such research is still continuing and many papers have been published; thus, it is impossible to even cite all the representative and important papers. It is suggested that interested readers refer to the excellent reviews on this research (e.g. in the works of Eisenthal, Chen et al., Bain, Richmond, Shen, and Gopalakrishnan et al.) and those original publications cited in these reviews.

After discussing the SFG studies on liquid surfaces and interfaces in the next section, relatively recent SFG results on polymers and biological molecules at interfaces will be discussed. Similarly, extensive excellent research has been performed in SFG studies on polymers and biological molecules and it is impossible to cover the entire research field. Instead, this paper will mostly focus on the research results from the Chen lab, with which the authors are most familiar.

3.1 Small Molecules at Interfaces Involving Liquids

3.1.1 Water/Air Interfaces

Compared to the surface analytical techniques that require high vacuum to operate, one of the most important advantages of SFG is that it can be used to study liquid surfaces and interfaces. Water is often considered to be one of the most important liquids, and it is important to understand water structures at surfaces and interfaces.

In 1993, Shen and his colleagues published their SFG studies on water surfaces in air. They assigned three major peaks in the SFG spectrum collected in the O–H stretching frequency range (Figure 3). The ∼3700 cm\(^{-1}\) peak is contributed by free O–H groups (or dangling O–H bonds). Such O–H groups stick out from water into the air; otherwise, they would form hydrogen bonds with other water molecules. The two other peaks centered at ∼3200 and ∼3400 cm\(^{-1}\), respectively, are hydrogen-bonded O–H stretching signals. Shen et al. referred to these two peaks as “ice like” (for ∼3200 cm\(^{-1}\)) and “liquid like” (for ∼3400 cm\(^{-1}\)) peaks, because they are close in positions with the stretch modes of the bonded O–H in bulk ice and water. However, the assignment for the 3200 cm\(^{-1}\) peak is still under debate. From the spectral fitting, it was found that the ∼3700 cm\(^{-1}\) peak has a different phase (for ∼3200 cm\(^{-1}\)) and “liquid like” (for ∼3400 cm\(^{-1}\)) peaks, showing that the hydrogen-bonded O–H groups are facing toward the water bulk. From the calibrated absolute signal intensity, it was deduced that more than 20% of the water molecules at the water/air interface have dangling O–H bonds.

It was found that the dangling O–H signal gradually decreased as methanol was mixed into the bulk water, and completely disappeared as the concentration reached 11% by volume. It was determined that there is a 0.25 monolayer of O–H dangling bonds at the water/air interface.

![Figure 3](image-url)  
**Figure 3** SFG spectrum collected from the pure water/vapor interface with ssp polarization combinations. Solid line is fitting result. (Reprinted figure with permission from Ref. 9. © 1993 by the American Physical Society.)
interface. When the dangling O–H bonds disappeared, the 3200 cm$^{-1}$ peak dominates the spectrum, showing that the interfacial water molecules at the interface after introducing methanol are much more ordered compared to those at the water/air interface. SFG spectra were again collected from the water/air interface recently using different polarization combinations. A new peak at $\sim$3600 cm$^{-1}$ was observed in the sfs spectrum, which is assigned to the peak with bonded O–H stretch mode of surface water molecules with one bonded O–H and one dangling O–H. Temperature-dependent SFG signals of the water/vapor interfaces were collected and no strong temperate dependence was observed. The most noticeable change was an increase of the peak around 3400 cm$^{-1}$ (disordered liquid-like peak). This is different from some simulations that predict a strong temperature dependence for the surface structure of water.

3.1.2 Water/Hydrophobic Media Interfaces

Shen et al. also studied water structures at an interface between other hydrophobic surfaces and water, for example, the interface between a layer of octadecyltrichlorosilane (OTS) and water, and hexane and water. At the OTS/water interface, free O–H signal has also been detected. The density of the O–H dangling bonds was measured and it was found that there is one dangling O–H bond in every four water molecules at the interface. This is similar to the water/air interface previously reported. Interestingly, comparing the SFG spectra collected from the OTS/water interface to the water/air interface, the 3200 cm$^{-1}$ peak intensity from the OTS/water interface is much stronger. At a hydrophobic solid/water interface, the surface water molecules form a more ordered ice like structure because of the physical restriction involved in packing molecules against a solid. While at the hexane/water interface, the water spectrum was more similar to that collected from the water/air interface. In addition to the hydrophobic surfaces, water structure at the interface between a partially wettable surface and water was studied using SFG. In this case, the dangling water signal disappeared.

To date, extensive research has been done on water surfaces and interfaces using SFG. Richmond et al. showed that water has a different structure at the CCl$_4$/water interface than at the water/air interface. At the CCl$_4$/water interface, the hydrogen-bonded O–H species shift to higher frequencies, indicating significantly weaker hydrogen bonding at the CCl$_4$/water interface. These hydrogen-bonded water molecules at the CCl$_4$/water interface have weaker interactions with other water and CCl$_4$ molecules, leading to a frequency shift. However, the free O–H bonds peak at the CCl$_4$/water interface shift to 3660 cm$^{-1}$ from the 3700 cm$^{-1}$ at the water/air interface. Richmond’s later research showed that this shift is the result of an attractive interaction between the dangling O–H bond and the surrounding CCl$_4$ molecules. Richmond also extensively investigated the effect of surfactant adsorption on water structure at interfaces. It was shown that the hydrogen bonding of water is highly sensitive to the presence of charged surfactants, with changes occurring in the water spectrum at trace concentrations in the aqueous solutions.

3.1.3 Solution/Air Interfaces

Shultz et al. studied water surface structure at the sulfuric acid as well as sulfate solution surfaces. Sulfuric acid and sulfate aerosols are known to play a central role in atmospheric chemistry. Stratospheric sulfate aerosols are the dominant staging surfaces for reactions involved in ozone depletion. The determination of the distribution and orientation of water on the surface for 40–80 wt% (0.1x 0.4x) sulfuric acid would greatly help assess plausible mechanisms for stratospheric processes. SFG spectra collected from the sulfuric acid solution in air indicated that the dangling water SFG signal was observed when a small amount of sulfuric acid was added to the water. However, when the solution contained 0.1x sulfuric acid, the free O–H signal was greatly reduced. No free OH signal was observed from the surface of solutions that contained a higher sulfuric concentration. The absence of this peak indicated a lack of dangling hydrogen atoms at the surface for stratospherically relevant concentrations. To determine whether the lower temperatures of the stratosphere result in greater partitioning of water to the surface, the SFG signal was examined as a function of temperature for a 0.2x solution. Neither hydrogen-bonded water (discussed in the next section) nor free OH water was significantly altered for temperatures as low as 216 K. This showed that the surface structure was not altered at a lower temperature. Shultz et al. also studied surface structures of water at the water-sulfate solution surface. SFG spectra collected from the water/air interface were compared to those from the aqueous solutions of H$_2$SO$_4$, LiHSO$_4$, CsHSO$_4$, and KH$_2$O$_2$ (keeping the anion concentration constant at 0.1x). For H$_2$SO$_4$, the SFG intensity increased, especially for the 3150 cm$^{-1}$ peak.

SFG signals from the sulfate solution surfaces showed a less dramatic but similar intensity increase. Schultz et al. believed that “this intensity increase is attributed to an electric double layer that arises in the solution due to the differential distribution of anions and cations near the surface. Here the anion is larger and more polarizable than the cations. The hydration shell of the cations is therefore more strongly associated than that of the anion, limiting the approach of the cation toward the surface.
Similarly, the greater polarizability of the anions results in a lower enthalpic drive of anions away from the interface. As a result, the tail of the anion distribution extends further toward the interface than that of the cation. This differential distribution gives rise to a double layer just below the surface, and the negative pole of the double layer is directed at the surface.” For smaller cations, for example H\(^+\) and Li\(^+\) studied here, along with HSO\(_4^-\) create a stronger field, and therefore a greater enhancement of the \(3150\ \text{cm}^{-1}\) peak. For the larger cations, K\(^+\) and Cs\(^+\) at 0.01 M, it is easier for them to form ion pair with HSO\(_4^-\) and penetrate to the surface. Because of the presence of the ion pairs on the surface, the O–H dangling bonds are reduced, resulting in weaker free O–H signals.

Shen et al. also studied water structure at the sulfuric acid/water interface; details can be found in Raduge et al.\(^{28}\) In addition to sulfate and bisulfate ions, water structure of halide ion solutions was investigated and compared to the theoretical simulations results. More details of the related research can be found in Gopalakrishnan et al.\(^{15}\)

Cremer et al. studied how the presence of different Hofmeister anions in the solution altered the water structure next to a polymer.\(^{29}\) Specifically, SFG spectra were collected from a solution surface with poly (N-isopropylacrylamide) (PNIPAM) on the surface (Figure 4). When different ions were added to the solution, the SFG signal from surface PNIPAM exhibited no change but the water signal changed substantially. The SFG signal contributed from O–H stretching was stronger for chaotropic anion solutions. The surface potential changes more for the chaotropic anion solution with PNIPAM on the surface – such results match SFG data quite well. Cremer et al. suggest that chaotropic anions segregate more easily to the solution surface to orient water to generate stronger SFG signals and induce bigger changes in surface potential. This is because “adsorption behavior can be viewed as a partitioning of the anions between the interface and the bulk solution. The equilibrium constant and the bulk concentration dictate the distribution between these two states. For an ion to be adsorbed at the interface, it needs to undergo partial desolvation. The chaotropic anions have relatively low solvation free energies mostly because of their generally large size and high polarizability.\(^{20}\) Therefore, a smaller desolvation penalty is paid compared with the kosmotropic anions.”

Ammonium is the only basic gas molecule that is important in environmental chemistry.\(^{25}\) SFG has been applied to examine surface structures of ammonium aqueous solution. It was interesting to observe that the free O–H peak at \(\sim3700\ \text{cm}^{-1}\) actually contained two components at the ammonium solution/air interface (Figure 5). The peak at \(3700\ \text{cm}^{-1}\) became narrower when as little as 0.005 M NH\(_3\) was added and disappeared with a concentration of 0.04 M. A broader peak extending about 100 cm\(^{-1}\) beginning at 3680 cm\(^{-1}\) was observed until 0.33 M NH\(_3\) was added. When looking at the N–H stretching at \(\sim3310\ \text{cm}^{-1}\), below 0.10 M, the ammonium resonance increased as the free O–H resonance decreases. The observation indicated that at low concentration ammonium titrated the free O–H bonds, simply docking to the dangling hydrogen through the ammonium long pair. When half of the free OH groups reacted with the ammonium, the decrease of the OH peak stopped until the ammonium concentration was doubled (\(>0.20\ M\)).
Figure 5  SFG spectra collected from ammonium solution surface: Free OH resonance of water (a) narrows and decreases with as little as 0.005x NH₃ (b) The broader resonance, shown for 0.10x NH₃ (c) persists to high concentration. (Reprinted with permission from Journal of Physical Chemistry B. © 2002 American Chemical Society.)

3.1.4 Water/Hydrophilic Solid Interfaces

Shen et al. studied the water structure at hydrophilic solid/water interfaces. For example, fused silica/water and crystalline quartz/water interfaces were investigated while varying the pH in water. Generally, the SFG spectra that were collected from the silica/water interface or quartz/water interface were similar to those collected from the water surface in air, except there was no O–H dangling bonds signal. Both ice like and liquid like hydrogen-bonded OH signals were detected, indicating that the interfacial water molecules again form a partially ordered hydrogen-bonded network. Both the ∼3200 and 3400 cm⁻¹ peaks increase with pH, but the ice-like peak grew appreciably at high pH, suggesting a better polar-ordered network at high pH. To determine the absolute orientation of O–H groups at the quartz/water interface at different bulk pH of water, Shen et al. developed a phase-sensitive method from which it was feasible to deduce the O–H orientations. The idea was to use the coherent property of the SFG technique to observe the interference between a bulk nonresonant SFG signal generated from crystalline quartz and the resonant SFG water signal. From such observed signal interference, it is feasible to deduce the phase information of SFG water signal; therefore, both real and imaginary components of the SFG signal from water can be deduced (Figure 6). It was found that the liquid like water maintained the same orientation when pH was varied, but the overall orientation of the ice like water flipped when the pH was increased. This technique of phase interference between a resonant signal of the analyte and a nonresonant background signal is a general method to measure the absolute orientation of interfacial molecules with SFG spectroscopy.

3.1.5 Charge Effect on Interfacial Water Structure

Richmond et al. studied the liquid/air interface of an aqueous solution with the surfactants sodium dodecyl sulfate (SDS), dodecylammonium chloride (dimethylammonium chloride, DAC), or a mixture of SDS and DAC (Figure 7). SDS and DAC carry negative and positive charges, respectively. When the surfactants were added to water, they segregated to the surface, forming a negatively or positively charged surface, inducing strong water ordering near the surface. The SFG water signal became very strong owing to the strong ordering. When the neutral SDS and DAC mixture was added, no SFG water signal was observed.

Chen et al. collected SFG spectra from a protein solution surface in air (Figure 8). When the pH was varied, the SFG water signal had different intensities. When the pH was substantially higher or lower than the isoelectric point of the protein, the protein adsorbed at the solution/air interface carries negative or positive charges, which can orient the water molecules near the interface. This ordering generates much stronger SFG water signal than when the solution pH is close to the protein isoelectric point. Clearly, interfacial charges greatly affect interfacial water ordering, and these changes can be detected using SFG.

3.2 Polymer Surfaces and Interfaces

The performance of many polymers is dominated by their surface properties, such as wettability, friction, lubricity, wearability, chemical reactivity, biological compatibility, biological activity, and permeability. These properties are widely used in many modern technological fields including biomaterials, microelectronics, display technology, coatings, and membranes for separations. Surface properties depend upon the chemical and physical details of the molecular structure at the polymer surface. In order to control surface properties by manipulating surface structure, we must have an extensive database of detailed correlations between properties and structures of the polymer surfaces.

SFG has been extensively applied to study molecular structures of surfaces and interfaces of a variety of polymer materials. In the following, after discussing
3.2.1 Quantitative Understanding of Polymer Surfaces

Polymers are large molecules and therefore polymer surface structures can be quite complicated. Before discussing how to quantify surface structures of polymer materials, a simpler surface, a surface of a self-assembled monolayer (SAM), for example, a methyl-terminated SAM on an Au surface will be discussed. Assuming the SAM surface has no defects, the surface is completely covered by terminal methyl groups. For an ideal sample, these methyl-terminated groups adopt the same orientation. Therefore, if the distribution of orientation angles of the methyl groups can be measured, it should be a delta distribution. If a surface is known to be completely covered by methyl groups, and if the orientation of all these methyl groups is deduced, the surface structure could be said to be understood quantitatively. Such quantitative structural information of a SAM surface can be obtained using SFG. SFG spectra collected from such a surface will show specific vibrational peaks for methyl groups, for example, 2875 cm$^{-1}$ for symmetric C–H stretching, 2960 cm$^{-1}$ for asymmetric stretching, and 2945 cm$^{-1}$ for Fermi resonance. According to the intensity ratio of the signals detected in SFG spectra using different polarization combinations, the orientation of the methyl groups can be deduced. It is difficult to prepare a “perfect” SAM sample. The defects in SAM can change orientation.
of some of the terminated methyl groups. The orientation distribution of the methyl groups cannot be described by a delta function then, but rather with a distribution with a certain width. If such an orientation distribution can be determined, then the surface with defects can be understood quantitatively.

A polymer surface may be more complicated and can have many different functional groups. The surface can also be quite disordered, meaning that the orientation distribution for each functional group can be very broad. A substantial number of different polymer surfaces have been investigated using SFG. It has been found that most polymer surfaces are dominated by one or two types of functional groups. If the surface-dominating functional groups can be identified, and if orientation distributions of these groups can be quantified, then the surface structure of these polymer materials can be quantified. Therefore, the quantification of polymer surface or interfacial structure can be realized by (i) identifying surface-dominating functional groups and (ii) deducing orientation distributions of such groups.

3.2.2 Sum Frequency Generation Studies on Polymer Surfaces in Water and Other Liquids

SFG has been applied to study surface structures of a variety of polymers in air. Examples of such polymers include polyethylene, polypropylene, various poly(methacrylates), polystyrene (PS), poly(dimethyl siloxane) (PDMS), poly(ethylene glycol), poly(propylene glycol), polyimides, nylon, poly(ethylene terephthalate) (PET), and polyurethane. SFG has also been used to study the surface structures of different polymer blends and copolymers. In addition, SFG has been applied to investigate structures of polymer surfaces in liquids and
buried polymer interfaces, which will be the focus of the discussion here.

Polymer materials are widely used in various liquid environments. For example, polymeric biomaterials are routinely implanted into human bodies. Antibiofouling polymer coatings for marine vessels are used in ocean. Surfaces of polymer membranes for biological molecule separation are exposed to biological molecule solutions when in use. To ensure the desired performance of these polymers, it is important to characterize the polymer surface structures in aqueous environments.

SFG has been developed into a powerful technique to characterize surface-restructuring behavior in liquid environments. SFG spectra can be directly collected from the polymer/liquid interface, probing polymer/liquid interface in situ in real time with a submonolayer sensitivity and surface specificity.

3.2.2.1 Polymer Side Chain Changes in Water – Polymethacrylates SFG spectra from poly (n-butyl methacrylate) (PBMA) surface in air, in water, and after removing the sample from water were collected using different polarization combinations (Figure 9). The SFG spectra collected from PBMA in air show different spectral features compared to those collected from PBMA in water, indicating that PBMA surface exhibits surface restructuring in water. The SFG spectra collected from the PBMA surface after removing it from the water and exposing to air again are similar to those collected before exposure to water, suggesting that the surface restructuring in water is reversible. The SFG spectra collected from PBMA in air and in water were both dominated by the signals contributed from methyl end groups of the ester chains. Comparing the symmetric and asymmetric methyl-stretching peak intensities in the spectra, it was determined that the methyl groups stand up more on the PBMA surface in air, and lie down more in water.

The SFG spectra collected using different polarization combinations can be used to deduce orientation...
information of surface functional groups. The SFG polarized spectra measure components of second-order nonlinear optical susceptibility, which are related to different components of hyperpolarizability of the vibrational mode through \( \langle \cos \theta \rangle \) and \( \langle \cos^3 \theta \rangle \), where “( )” means the average, and for methyl, \( \theta \) is the angle between the principal axis of the methyl group and the surface normal. By measuring SFG spectra intensity in different polarization combinations, the ratio between \( \langle \cos \theta \rangle \) and \( \langle \cos^3 \theta \rangle \) can be determined. Assuming that every methyl has the same orientation – a delta orientation distribution – the orientation angle \( \theta \) can be deduced. However, it is impossible to deduce \( \langle \cos \theta \rangle \) and \( \langle \cos^3 \theta \rangle \) individually with this ratio. In addition to collecting the SFG spectra using different polarization combinations, the absolute intensity can also be calibrated. With the help of absolute intensity, it is possible to deduce both \( \langle \cos \theta \rangle \) and \( \langle \cos^3 \theta \rangle \).

By assuming a Gaussian distribution for the orientation distribution of methyl groups, the orientation distributions of methyl groups on the PBMA surface in air and in water (Figure 10) can be determined. Figure 10 shows that methyl groups have a broader orientation distribution but a smaller average orientation angle in air. Methyl groups stand up more on the surface in air, and the surface is quite disordered (because methyl groups can have a broader range of orientation). In water, the orientation distribution is narrower, showing that the PBMA surface in water is more ordered. The average orientation angle of methyl on the PBMA surface in water is smaller, indicating that they lie down more toward the surface – perhaps due to the unfavorable interaction with water molecules.

To deduce the orientation distribution, it was assumed that the orientation distribution was a Gaussian function. To generalize this methodology for orientation distribution determination, a different trial function called the maximum entropy function was used.\(^{24}\) Mathematically it has been proved that such a maximum entropy function leads to minimum bias under a limited amount of measurements. The orientation distribution deduced by using the maximum entropy function is similar to that of Gaussian function, showing that Gaussian function was a good approximation in this study.

In addition to the PBMA, other polymethacrylates with different side chain lengths in water were studied. Some of them exhibit similar surface-restructuring behaviors as PBMA, including poly (ethyl methacrylate) (PEMA), poly (propyl methacrylate) (PPMA), and poly (hexyl methacrylate) (PHMA).\(^{31}\) Similar to PBMA, the orientation distributions of surface-dominating end methyl groups on PPMA, PHMA, and poly (octadecyl methacrylate) (PODMA) surfaces were deduced. The methyl end groups of the side chain tend to stand up with a broader distribution in air and lie down more with a narrower orientation distribution in water. They have very similar average orientation angle or orientation distribution in air, but small difference of the methyl group orientation on the PPMA, PBMA, and PHMA surfaces in water was observed (Figure 11). With the increase of the side chain length, the orientation angle increased with a narrower orientation distribution.\(^{31}\)

The surface structural changes in water for PODMA were different. The average orientation angle and orientation distribution of surface-dominating methyl groups vary only slightly. It was found that PODMA was semicrystalline and therefore the surface was quite rigid and only small orientation changes of surface methyl groups were detected. The research in this section demonstrates that it was feasible to study surface-restructuring behaviors of polymeric materials in water quantitatively.\(^{24,31}\)

3.2.2.2 Polymer Side Chain Changes in Water – Poly (dimethyl siloxane) PDMS surfaces also exhibit side chain orientation changes in water. PDMS, a good candidate for marine antibiofouling coating, has been extensively studied since the early 1970s.\(^{32–34}\) However, understanding of its molecular surface structure in the aqueous environment in situ has not been achieved. Different types of PDMS materials can have different antibiofouling properties, because of their different surface structures. To elucidate the biofouling control and release properties of PDMS and their relation to molecular surface structures, SFG was used to examine molecular surface structures in air and surface-restructuring behavior in water of three different types of PDMS materials.\(^{35}\) They were tetraethoxysilane-cured hydroxy-terminated poly(dimethyl siloxane) (TEOS-PDMS), platinum-cured vinyl-terminated poly(dimethyl siloxane) (PDVS-PDMS), and tetraethyl orthosilicate-cured hydroxy-terminated poly(dimethyl siloxane) (TEOS-PDMS).

![Figure 10](image-url) Figure 10: Orientation distribution of methyl groups on the PBMA surface in air and in water. The angle in the x axis is the angle between the methyl principal axis and the surface normal. In air, the methyl groups have a small average angle, showing that they like to stand up on the surface with a broader distribution. In water, they tend to lie down with a narrower distribution (Reproduced with permission from Ref. 24. Copyright 2002, American Chemical Society.)
siloxane) (Pt-PDMS), and poly(dimethyl siloxane)-co-poly styrene (PDMS-co-PS) copolymer.

Using different polarization combinations of input and output light, SFG spectra were collected from the three PDMS surfaces in air as shown in Figure 12. All the SFG spectra were dominated by SFG signals contributed by the methyl groups on the PDMS side chains, showing that all surfaces are dominated by methyl groups. For Pt-PDMS, there are weak SFG signals due to the presence of \(-\text{Si}--\text{CH}_2--\text{CH}_2\) moieties at cross-linking points on the surface. In the spectra collected from the PDMS-co-PS surface, there are several peaks above 3000 cm\(^{-1}\) that correspond to the aromatic C–H stretches from the phenyl group, indicating that on this surface, in addition to the methyl groups, phenyl groups also have some surface coverage. This research shows that small differences in surface structures of PDMS materials can be seen with SFG spectroscopy.

Surface-restructuring behaviors of these three PDMS materials in water were studied (Figure 13). For comparison, their surface changes in a hydrophobic fluorinated solvent, FC-75, was also studied. The SFG spectra collected from the three PDMS/water interfaces were very different from those of the PDMS/air interfaces. This would indicate that surface restructuring occurred in water. SFG data analysis indicated that when the hydrophobic PDMS surface contacted water the surface groups tended to reorganize by tilting more toward the surface to minimize interfacial free energy. At the PDMS-co-PS/water interface, the SFG signals due to methyl group stretches disappeared (Figure 13c) and only the signals due to the phenyl group stretches were visible. The disappearance of the methyl group stretches demonstrated that the methyl groups may reorganize differently at the PDMS-co-PS/water interface than at the other two PDMS/water interfaces. The similarity in the SFG signals due to the phenyl group stretches at the PDMS-co-PS/air, water, and FC-75 interfaces indicated that the phenyl groups do not experience restructuring when the film contacted different solvents.
Quantitatively, SFG results showed that the methyl groups at the Pt-PDMS/water interface tilt more toward the surface than those at the TEOS-PDMS/water interface. Unlike TEOS-PDMS or Pt-PDMS, the PDMS chains on the PDMS-co-PS surface are more mobile owing to the absence of cross-linked networks. Therefore, the molecular reorganization on the PDMS-co-PS/water interface became more complete and the interface was totally covered by the Si–O backbone, causing no SFG signals to be detected from the methyl group vibrational modes.

The SFG spectra collected from PDMS/FC-75 interfaces were more similar to the spectra from PDMS surfaces in air than those from PDMS/water interfaces. Detailed analysis of such SFG spectra showed clearly that in FC-75 methyl groups orient more toward the surface normal than those in air.

Through this study, the molecular-level chemical structures of several different PDMS surfaces in air and in liquid environments were studied using SFG. SFG can detect small differences in the surface structures of different PDMS surfaces, which cannot be differentiated by other techniques. Such molecular-level understanding of PDMS surface structures in various environments can provide detailed understanding of differences in antifouling properties of these PDMS materials. Previous research indicates that Pt-cured and alkoxysilane-cured PDMS have different stability in water and different antifouling performance.\(^\text{[36]}\) Such differences should be caused by the different surface structures revealed by SFG. This research demonstrates that SFG is a powerful in situ technique to characterize surface structures of biofouling control/release polymer.

### 3.2.2.3 No Detectable Surface Restructuring in Water

Other polymer surface-restructuring behaviors were also detected. The SFG spectra collected from the polymethylmethacrylate (PMMA) surface in water using different polarization combinations have similar spectral features to those collected in air, but weaker intensities.\(^\text{[37]}\) Calculations indicated that the weaker intensities were due to the different refractive indices of water and air, rather than changes in the surface structures. PMMA surfaces were dominated by the ester methyl groups, and surface-dominating ester methyl groups did not exhibit detectable structural changes in water. This may be due to two reasons: (i) PMMA has a high glass transition temperature and therefore PMMA molecules including those on the surface are not very mobile and (ii) the ester methyl groups were more hydrophilic compared to the normal methyl groups. The ester methyl groups have a more favorable interaction with water than normal methyl groups.

### 3.2.2.4 Irreversible Polymer Surface Restructuring

For methacrylates with longer side chains, such as poly \(n\)-octyl methacrylate (POMA) and poly (lauryl methacrylate) (PLMA), the SFG spectra collected in air indicated that their surfaces in air were still dominated by side chains.\(^\text{[31,37]}\) However, substantial methylene signals can also be detected. Longer side chains have more gauche defects, generating stronger methylene signals. SFG signal was not detected from the polymer/water interface for POMA and PLMA, because the interfaces were totally disordered. The results showed that POMA and PLMA surfaces exhibit significant restructurings. The SFG spectra collected from the sample surface after removing the sample from water and exposing to air again did not completely recover. Both POMA and PLMA have very low glass transition temperatures (\(-20\) and \(-65^\circ C\) respectively), meaning the molecules can be very mobile and thus their surfaces exhibit substantial irreversible changes in water.

The SFG study of poly(ethyl acrylate) (PEA) showed that PEA had a similar surface-restructuring behavior as POMA and PLMA.\(^\text{[38]}\) Like POMA and PLMA, PEA also has a very low glass transition temperature of \(-21^\circ C\).
The SFG spectra were also collected from the surface of a PDMS sample that was not fully cured. In air, the SFG spectra were similar to those collected from fully cured PDMS, indicating that the surface was dominated by SiCH₃ groups. No SFG signal was detected from the surface in water. The SFG spectra collected from the sample surface after removing the sample from water and exposing to air again did not completely recover. These observations differ from those of the fully cured PDMS materials, but were similar to those of POMA, PLMA, and PEA. It was suggested that this is due to the surface molecules of non fully cured PDMS being quite mobile. From the studies presented in this section, it is suggested that highly mobile molecules on the polymer surfaces in air can become totally disordered in water. After removing the polymer surface from water, the surface structure cannot recover.

### 3.2.2.5 Slow Surface Restructuring in Water

For polymers discussed above, except for PMMA, which does not exhibit a detectable surface change in water, all other polymer surfaces exhibit restructuring behaviors immediately after contacting water. SFG research has shown that for some polymers surface restructuring can be a slow process. Somorjai et al. studied surface structural changes of a polyurethane with PDMS end groups in water. This type of polymer has been used as a biomedical material. In air, because the PDMS silicone end groups are more hydrophobic, they cover the surface. When exposed to water, the more hydrophilic polyurethane backbone gradually segregates to the surface. SFG studies showed that after about 25 h the surface was dominated by the polyurethane backbone.

Chen et al. studied surface structural changes of a commercial polymer Sylgard 184 (unpublished results). As model PDMS surfaces that were discussed above, the Sylgard surface was also dominated by the SiCH₃ groups in air. Surface restructuring was detected after Sylgard surface was contacted with water. When the surface was removed from water and exposed to air again, the SFG spectra gradually recovered. The recovery process took tens of minutes.

### 3.2.2.6 Summary of Sum Frequency Generation Studies on Polymer Surfaces in Water

Many important applications of polymers involve placing them in aqueous environments. Examples include biomedical polymer implants, marine biofouling coatings, polymer membrane for separation, and polymer coating for biosensors. Owing to the lack of applicable analytical techniques, some previous research studied polymer surface structures in air or in vacuum, and assumed that such surface structures are the same in water. It has been shown recently that SFG can probe molecular-level surface structures of polymers in situ in real time. SFG results indicated clearly that different polymer surfaces can exhibit varied restructuring behaviors. Some polymer surfaces showed reversible side chain orientation changes, others showed no surface change, and still others exhibited irreversible backbone changes. SFG results demonstrated that the assumption that polymer surface structures in air and in water are the same is not always a valid one.

Detailed surface-restructuring behaviors of various polymer surfaces in water revealed by SFG provide excellent experimental evidence for theoretical simulations. Chen et al. showed that molecular dynamics simulations of PS (using ethyl benzene as a PS model) surface in water (unpublished results) match SFG results quite well (unpublished results).

### 3.2.3 Sum Frequency Generation Studies on Buried Interfaces Involving Polymers to Understand Polymer Adhesion

#### 3.2.3.1 Introduction

Adhesion to polymer materials is important in many areas such as the automotive industry, aviation and aerospace, construction, electronics, industrial assembly and maintenance, paints and inks, and beauty and personal care. For example, adhesives for polymers ensure the reliability and durability of coatings. Also, adhesives reduce the weight of a spacecraft by eliminating mechanical fasteners such as rivets. Similarly, from aircraft to automobiles to marine vessels, replacing rivets and bolts with adhesives will greatly reduce the vehicle weight and thus the amount of operation fuel, which is vital in energy conservation, environmental protection, and cost reduction. Adhesives also help distribute stresses over a wide area. Some other examples of the wide application of adhesion of polymer materials are in drug delivery, scar therapy, specialty cosmetic and hair replacement, and wound care products. However, up to now the molecular-level understanding of adhesion mechanisms at polymer surfaces/interfaces has not been fully developed, which obstructs the systematic design of adhesives with the required performance.

For polymer adhesion applications, there is an increasing demand for silicone-based materials that can adhere to plastics, without surface priming or pretreatment. Silicone elastomers are widely used because of their unique rheological properties, purity, and unsurpassed thermal stability and flexibility at a wide range of temperatures. In particular, hydrosilylation- or addition-cured silicones offer advantages because of their clean cure chemistry and controllable and rapid cure kinetics. However, unlike condensation cure reactions, hydrosilylation-cured siloxanes are not naturally enriched...
with polar, moisture-reactive groups and generally require the addition of adhesion-promoting additives.

Silane adhesion promoters are well suited for metals and other inorganic substrates that have reactive hydroxyl functional groups at their surfaces. Research also showed that alkoxysilane-based adhesion promoters could be quite effective in addition-curing silicones for imparting adhesion to some engineering thermoplastics, but the molecular mechanisms for such adhesion are not known.\textsuperscript{45} Chen et al. studied the molecular structures of the silane molecules at buried polymer interfaces to understand the mechanisms of adhesion.

3.2.3.2 Molecular Structures of Silanes at Polymer/Silane Interface Chen et al. studied interactions at the interface between various polymers and different silanes. SFG spectra were directly collected from polymer/silane interfaces in situ.\textsuperscript{46} The initially examined polymers include PMMA and PS. To avoid spectral confusion, deuterated PMMA (d-PMMA) and d-PS were used in the experiment. Chen et al. observed different structures of various silanes contacting PMMA or PS. The surfaces of both PMMA and PS are dominated by the ester methyl and phenyl groups, respectively.\textsuperscript{17,47,48} The silanes that Chen et al. studied are n-octadecylchlorosilane (OTC, CH\textsubscript{3}(CH\textsubscript{2})\textsubscript{17}SiCl\textsubscript{3}), and n-octadecyltrimethoxysilane (OTM, CH\textsubscript{3}(CH\textsubscript{2})\textsubscript{17}Si(OCH\textsubscript{3})\textsubscript{3}).

The polymer/OTC and polymer/OTM interfacial SFG spectra did not change with time, indicating that these interfaces were stable. Different interfacial structures of silanes could be deduced by spectral analyses (Figure 14, see Chen et al.\textsuperscript{46} for more details), and Chen et al. suggested that such structures were determined by the molecular interactions of the functional groups at these interfaces.\textsuperscript{46} For example, the d-PMMA/OTC interface was dominated by the OTC methyl end groups as there were favorable interactions between these groups and the surface-dominating ester methyl groups of PMMA. At the PMMA/OTM interface, methoxy groups segregate to the interface that interacted more favorably with the PMMA ester methyl groups. At the PS/OTC interface, the OTC methylene backbones dominate the spectra. At the PS/OTM interface, both methoxy and methylene groups are detected. The restructuring of the ester methyl groups of PMMA and phenyl groups of PS at these different interfaces was also examined. This research clearly demonstrated that silane molecules adopt varied conformations at polymer/silane interfaces owing to different interfacial molecular interactions.\textsuperscript{46}

3.2.3.3 Diffusion of Silanes into Polymers SFG was also applied to investigate structures of amino silane at the polymer/silane interface. Two amino silanes, 3-aminopropyltrimethoxysilane (ATM, NH\textsubscript{2}(CH\textsubscript{2})\textsubscript{3}Si(OCH\textsubscript{3})\textsubscript{3}) and N-(2-aminoethyl)-3-aminopropyltrimethoxysilane (AATM, NH\textsubscript{2}(CH\textsubscript{2})\textsubscript{2}NH(CH\textsubscript{2})\textsubscript{3}Si(OCH\textsubscript{3})\textsubscript{3}) were studied.\textsuperscript{46,49} The SFG spectra collected from the polymer/silane interfaces when either ATM or AATM were contacted at the PMMA or PS surfaces changed with time and finally decayed to zero. The signal disappearance at the PS interface is because ATM and AATM can dissolve PS. For PMMA, Chen et al. suggested that this phenomenon was due to strong interactions between the silane amino groups and the PMMA surfaces, resulting in the diffusion of the ATM and AATM molecules into the polymer. The diffusion of silane molecules was confirmed by a polymer bilayer experiment.\textsuperscript{49} More specifically, the diffusion of AATM through the d-PMMA film was confirmed by SFG studies on the interface between AATM and a d-PMMA/PS two-polymer layer system. Initially the SFG signal from the PS layer was detected. However, after AATM diffused through the d-PMMA film, the PS film was dissolved by the silane, and thus the SFG signal from PS was lost. Chen et al. demonstrated that interdiffusion occurs much faster at the PMMA/ATM interface than at the PMMA/AATM interface. Using d-PMMA films of different thickness, Chen et al. showed that SFG could be used to monitor the chemical structures of moving interfaces during diffusion and to quantitatively deduce the diffusion coefficient (Figure 15). For AATM diffusion into PMMA, the diffusion coefficient was determined to be \((3.80 \pm 0.39) \times 10^{-13} \text{ cm}^2 \text{s}^{-1}.\textsuperscript{49}

SFG results also showed that (3-glycidoxypropyl)trimethoxysilane (γ-GPS, Figure 16) can diffuse through the d-PMMA film.\textsuperscript{50} The diffusion of γ-GPS through the d-PMMA film was also confirmed by the polymer bilayer experiment. Similar experiments were carried out at the

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure14.png}
\caption{Schematic representations of different silane molecules oriented at the polymer/silane interfaces. The molecular segments (headgroup, backbone, and end group) of the silane molecules are represented as described by the legend. The boxes represent the bulk silane liquid. The SFG signals detected are primarily contributed from the molecular segments at the polymer/silane interfaces, that is, from those segments between the polymer substrate and the bulk. ○-CH\textsubscript{3}, ○-CH\textsubscript{2}-backbone, •-Si, ○ Cl, ○-OCH\textsubscript{3} (Reproduced with permission from Ref. 46. Copyright 2003, American Chemical Society.)}
\end{figure}
interface between a silane adhesion–promoting mixture (SAPM) of $\gamma$-GPS and a methylvinylsiloxnanol (MVS, $n = 9$) (Figure 16) and the d-PMMA/PS two-polymer layer system. It was found that the diffusion time of the $\gamma$-GPS in the SAPM through the d-PMMA film was significantly longer.

3.2.3.4 Hydrogen Bond Formation at the Interface AATM and ATM did not diffuse into all polymer films. For example, stable SFG spectra were detected from PET/ATM interfaces (Figure 17). (51) The shift of the C=O stretching frequency at the PET/ATM interface compared to the PET/air interface indicated the formation of hydrogen bonds between the ester carbonyl groups on the polymer surface and the amino groups of ATM. Detailed analyses of the SFG signals in the C–H stretching region collected from the PET/ATM and PET/BTM interfaces revealed that the conformation of ATM molecules at the interface is different from that of n-butyltrimethoxysilane (BTM). Even though SFG signals of methoxy headgroups were observed from both PET/ATM and PET/BTM interfaces, using the phase analysis previously mentioned in this paper it was shown that the methoxy adopt different orientations at the PET/ATM and PET/BTM interfaces (Figure 18). (51)

3.2.3.5 Molecular Structures of Silane Mixture at Polymer/Silane Interface Chen et al. applied SFG to study interfaces between polymers such as PET and PS, and SAPM. (52) Adhesion tests at Dow Corning Corporation showed that a PDMS elastomer containing the mixture could effectively adhere to PET after curing at 150 °C. Incorporating the silane or the siloxane alone into the elastomer did not achieve good adhesion under the same cure conditions. At the PET/$\gamma$-GPS interface, weak methoxy signals were detected using SFG. It was found that the initial SFG signal collected from the PET/mixture interface was also weak; however, it grew with time indicating that the silane methoxy headgroups adopted a much different final orientation or orientational order at this interface than at the polymer/$\gamma$-GPS interface. This observation may be used to interpret the different adhesion behavior between the mixture and the single component. Also the SFG signals arising from the mixture were not the same at different polymer interfaces. (52)

3.2.3.6 Preliminary Results of Silanes at Silicone/Plastic Interface SFG spectra of the adhesion-promoting system at the buried silicone/PET interfaces were successfully detected. (53) When adhesion-promoting molecules such as $\gamma$-GPS or SAPM were incorporated into the silicone, the segregation of the silane methoxy headgroups were detected at the interface even when the bulk concentration of silane in the silicone is 1.5 wt%. Comparing SFG spectra from samples that were cured for different lengths of time suggests that there was interaction between the $\gamma$-GPS with the $d_4$-PET surface at the polymer/silicone elastomer interface. Diffusion of the silane into the polymer was discounted and the data suggest that both interfacial ordering and reactions may play roles in adhesion in this particular system. When other silanes were incorporated into the silicone, the methoxy headgroups were either not present or not ordered at the $d_4$-PET/elastomer interface.

Figure 15 (a) Dependence of the SFG signal intensity at 2840 and 2945 cm$^{-1}$ collected from the d-PMMA/AATM interface as a function of the d-PMMA film thickness. The time taken by the AATM molecules to diffuse through the entire film increases with film thickness. The SFG signal can be detected during the diffusion process, showing that the moving interface is ordered. (b) Fitting of the diffusion time versus the d-PMMA thickness curve via a Fickian Model allows the diffusion coefficient to be deduced (Reproduced with permission from Ref. 49. Copyright 2004, American Chemical Society.)

Figure 16 Molecular formulas for (3-glycidoxypropyl)trimethoxysilane ($\gamma$-GPS) and methylvinylsiloxnanol (MVS, $n = 9$).
3.2.3.7 Summary From these SFG investigations on interfacial silanes, Chen et al. demonstrated that SFG is a powerful technique to elucidate polymer surface structures and polymer–silane interactions. It was observed that different silane structures at various interfaces were determined by the molecular interactions between the polymer surface functional groups and the functional groups that the silane were composed of, and certain silane molecules can diffuse into polymers. Chen et al. showed that hydrogen bonds formed between plastics and silanes, and mixing siloxane oligomers with silanes changed the silane structure at the plastic/silane interfaces.

3.3 Sum Frequency Generation Studies on Proteins and Peptides at Interfaces

3.3.1 Introduction

ATR-FTIR has been extensively applied to study the interfacial orientation of peptides and proteins through investigations on amide I signals. Amide I signals contain abundant information about protein backbone secondary structures. It has been shown that the amide I signal shifts frequency depending on secondary structure (see Raman Spectroscopy in Analysis of Biomolecules; Vibrational Optical Activity of Pharmaceuticals and Biomolecules; Biomolecules Analysis: Introduction; Circular Dichroism in Analysis of Biomolecules; Two-dimensional Vibrational Correlation Spectroscopy in Biomedical Sciences; Infrared Spectroscopy of Biological Applications). Initially, most SFG studies on interfacial proteins were based on the C–H and N–H stretching ranges, which are mainly contributed by protein side chains, due to instrument limitations. More recently, SFG has been used to study interfacial protein backbone structure/conformation using amide I signals.

SFG has several distinct advantages over conventional ATR-FTIR. The intrinsic surface sensitivity of SFG ensures that SFG only probes proteins/peptides at the interface with no interference from signals contributed from proteins/peptides in the bulk environments. Unlike in FTIR, water-bending modes contribute almost no SFG signal; therefore, SFG amide I signals exhibit no water signal interference. It is necessary to subtract a very large background to obtain the FTIR spectra of interfacial proteins/peptides and this may introduce substantial errors. By collecting SFG spectra using different polarization combinations of these beams, much more structural information can be acquired. SFG is a coherent spectroscopy, and various vibrational modes can interact with each other. Thus, unlike FTIR, SFG spectral-fitting results can be tested experimentally. Site-selective isotope labeling not only shifts the SFG peak of the site but also breaks the local symmetry to make the signal more prominent.

3.3.2 Advantages of Combining Multiple Vibrational Techniques in the Study

Different vibrational spectroscopic techniques measure different structural parameters. For example, if the tilt angle of a structural element (e.g. an α-helix) is θ versus the surface normal, ATR-FTIR can determine the angle through measuring \( \langle \cos^2 \theta \rangle \). For ATR-FTIR,
this is the only measurement obtained and can only be used to determine one structural parameter. Therefore, to understand the orientation of the functional group, it must be assumed that all the groups at the interface adopt the same orientation or a δ-orientation distribution. In contrast, SFG can measure both \( \langle \cos \theta \rangle \) and \( \langle \cos^3 \theta \rangle \). Thus, SFG can be used to deduce two different structural parameters, for example, orientation and distribution (assuming a Gaussian distribution function). However, if a chemical functional group adopts three different orientations (e.g., one protein has three \( \alpha \)-helices, each with a different orientation in the membrane), then the two SFG measurements are not enough. By combining SFG and ATR-FTIR measurements, however, it should be possible to deduce such distributions.

In the future, four-wave mixing (FWM) spectroscopy, which measures \( \langle \cos^2 \theta \rangle \) and \( \langle \cos^4 \theta \rangle \), could also be included in the study. FWM has the same selection rules as traditional Raman scattering, which are different from those of ATR-FTIR. Thus, FWM may measure \( \langle \cos^2 \theta \rangle \) through different vibrational modes from ATR-FTIR. FWM may be used to confirm ATR-FTIR results. In addition, FWM can measure \( \langle \cos^4 \theta \rangle \). More measurements can be used to deduce the orientation distribution more accurately, providing a more complete picture.

Figure 19 shows three cases for two \( \alpha \)-helices in a protein: they have the same tilt angle, 30° versus the membrane normal, but different absolute orientations. ATR-FTIR can measure their tilt angle but cannot differentiate the three cases. SFG can differentiate these three cases: the top and bottom cases can generate strong SFG signals, while for the middle case no SFG signal can be observed owing to the inversion symmetry of the two helices. The top and bottom cases can be differentiated by collecting SFG spectra interfering with a nonresonant or resonant signal of a known phase, from which the absolute “up” and “down” orientations of the two helices can be deduced. From SFG alone, the orientation of the helices in the middle panel cannot be determined; the only information is that two helices have opposite orientation or they both lie down on the surface. If SFG measurements are combined with ATR-FTIR data, the orientation of the two helices in the middle panel can be determined: one tilts 30° up and the other 30° down. Therefore, the combined vibrational spectroscopic studies can lead to the determination of more structural information.

When the protein crystal structure is known, it might be possible to deduce the membrane orientation of the entire protein from the orientation of the \( \alpha \)-helical secondary structure, allowing a greater understanding of how membrane proteins function. When the crystal structure is not known, measuring orientations of secondary structure elements may help understand the overall structure. Assuming a protein contains several secondary structural motifs, if the orientation of each secondary structure can be measured, then the “general” or “rough” structure/conformation of this protein may be determined (Figure 20). More detailed structure can be achieved if structural information of connections (e.g., coils) between different secondary structural motifs can be further measured (e.g., by isotope labeling). As presented above, when a protein has multiple \( \alpha \)-helices, it is difficult.

Figure 19 Combined SFG and ATR-FTIR studies can provide more detailed orientation.

Figure 20 The model protein has three \( \alpha \)-helices and several \( \beta \)-sheets. If the orientations of such secondary structures can be deduced, the rough structure or conformation of the protein can be known. A more detailed structure can be understood if the structural information of connections between different secondary structures is achieved.
to measure their orientations using ATR-FTIR alone. The combined SFG, ATR-FTIR, and FWM approach would generate more experimental measurements to deduce more detailed orientation distributions and more complicated structural information.

3.3.3 Maximum Entropy and Quantitative Analysis of Complicated Orientation Function

From a mathematical point of view, the task of reconstructing a distribution from its measured orientational parameters (e.g. \( \langle \cos \theta \rangle \)) is known as an inverse problem. It has been shown that the maximum entropy function, 
\[
G_{\text{total}}(\theta) = \exp \left( \sum_{n=0}^{N} a_n \cos^n \theta \right),
\]
is the best choice for a limited number of measurements, in the sense that it uses the fewest assumptions about the system.

To demonstrate the power of using multiple measurements, a few examples using artificial distributions will be discussed next. The first example is to assume that 
\[
G_{\text{total}}(\theta) = \exp \left( \sum_{n=0}^{N} a_n \cos^n \theta \right)
\]
is a Gaussian distribution with \( \theta_0 = 85^\circ \) and \( \sigma = 30^\circ \). This could be the distribution of \( \alpha \)-helical peptides at an interface with varied orientation of the \( \alpha \)-helix. The second function is a sum of two Gaussian distributions with \( \theta_1 = 35^\circ, \sigma_1 = 10^\circ \), \( \theta_2 = 135^\circ \), and \( \sigma_2 = 10^\circ \). Such a function could occur from the two coiled-coils in an interfacial fibrinogen molecule. The third example assumes 
\[
G_{\text{total}}(\theta) = \exp \left( \sum_{n=0}^{N} a_n \cos^n \theta \right)
\]
to be a combination of four \( \delta \) functions. A possible physical meaning for the third function could be a monolayer of ordered molecules on a surface. In each molecule, there are four identical chemical groups (e.g. \( \alpha \)-helices), which cannot be separated in the frequency domain, but they have different orientations versus the surface normal. The functions 
\[
G_{\text{total}}(\theta)
\]
assumed in the above three examples have the same average angle (85°) but have totally different orientation distributions. With one measurement (e.g. ATR-FTIR alone) only the average orientation angle can be measured, and the differences among these three cases cannot be observed. One measurement is far from adequate to differentiate the functions in these three examples. As mentioned above, using various vibrational techniques, it is possible to measure the following parameters: \( \langle \cos \theta \rangle \), \( \langle \cos^2 \theta \rangle \), \( \langle \cos^3 \theta \rangle \), and \( \langle \cos^4 \theta \rangle \).

The deduced functions for the above three hypothetical examples using different numbers of measurements are shown in Figure 21.\(^{(55)}\) From this figure, the deduced functions from one measurement (e.g. ATR-FTIR measurement) do not match any of the three real distribution functions. However, with more independent parameters deduced from other experiments, the deduced function can be much closer to the real function. With more measurements, even the case of a complicated distribution with four peaks can be resolved. Certainly, if there is preliminary information regarding these four peaks, for example, if it is known that there are four peaks and each one is a delta function, then only four independent measurements are needed to deduce such a four-peak distribution. This can be the case for membrane proteins; they may more or less have the same orientation. Thus, it is reasonable to assume the distribution of each type of \( \alpha \)-helical structure to be a \( \delta \) distribution. In addition to the application of combined vibrational spectroscopy, isotope labeling and controlled perturbation of interfacial peptides/proteins can generate additional independent measurements, providing more orientational parameters to deduce complicated orientation distribution.

3.3.4 Sum Frequency Generation Applications

3.3.4.1 Feasibility of Detecting Sum Frequency Generation Amide I Signals

Chen et al. demonstrated that it was feasible to collect SFG amide signals from protein molecules at interfaces in situ, allowing for the determination of backbone conformations of interfacial proteins using SFG.\(^{(56)}\) To ensure that SFG can detect amide I signals from interfacial proteins, a near-total-reflection sample geometry was adopted (Figure 22). It was clear that the SFG amide I bands from the various proteins were quite different, indicating that secondary structures of various interfacial proteins were different.\(^{(56)}\)
3.3.4.2 Feasibility of Distinguishing Protein Secondary Structures Using Sum Frequency Generation Amide I Signals  
After demonstrating the feasibility of detecting SFG amide I signals, Chen et al. further showed that these signals can be used to distinguish various protein secondary structures\(^\text{(57)}\) (see Biomedical Spectroscopy: Introduction).

**α-helical Structure**  
MSI-594 (Figure 23a and b) is an analog of the magainin 2 peptide. Figure 23(c) shows the SFG amide I signal collected from MSI-594 at the PS/solution interface. The main amide signal is centered at about 1650 cm\(^{-1}\), showing that the α-helical structure of MSI-594 dominates.\(^\text{(57)}\) The SFG spectrum can be fitted quite well using a single vibrational peak and a nonresonant background. For the fitted result, the peak center is at 1650 cm\(^{-1}\). The SFG amide I signal collected from magainin 2 at the PS/magainin 2 solution interface is also centered at \(~1650\) cm\(^{-1}\), indicating an α-helical structure (not shown). SFG amide signals from fibrinogen at various polymer/fibrinogen solution interfaces were detected.\(^\text{(58,59)}\) The signals were also dominated by a peak centered at 1650 cm\(^{-1}\) owing to the contribution of two α-helical coiled-coils. In addition to the peak center, it was confirmed that this peak was dominated by α-helical contributions using SFG polarization analysis.\(^\text{(58,60)}\)

**β-sheet Structure**  
Chen et al. demonstrated experimentally that SFG amide I signals could be detected from β-sheets.\(^\text{(57,61)}\) Figure 24(b) shows the SFG amide I spectrum collected from tachyplesin I at the PS/solution interface and the fitting results. Tachyplesin I is known to have a β-sheet structure in aqueous environments and in membranes. The β-sheet structure of tachyplesin I is robust because such a structure is held by two disulfide bonds (Figure 24a). Therefore, Chen et al. believed that it should maintain a β-sheet structure at the PS/solution interface. The fitting results of Figure 24(b) showed three major peaks at 1645, 1664, and 1688 cm\(^{-1}\), with several minor peaks at lower wavenumbers. Figure 24(c) displays the SFG spectrum collected from the PS/solution interface after the addition of dithiothreitol (DTT) to the solution. DTT reduced the two intramolecular disulfide bonds,\(^\text{(62)}\) which are essential for tachyplesin I to maintain its β-sheet structure (Figure 24d). After the addition of DTT the 1688 cm\(^{-1}\) peak disappeared. As discussed in many published papers, amide I signals at 1688 and 1633 cm\(^{-1}\) can be ascribed to the \(B_1/B_2\) and \(B_2\) modes of antiparallel β-sheets, respectively.\(^\text{(63–65)}\) The disappearance of the 1688 cm\(^{-1}\) peak upon the addition of DTT confirmed that this peak was generated by the β-sheet structure of tachyplesin I at the interface. Chen et al. further showed that SFG chiral spectra could be collected from interfacial tachyplesin, and such chiral

Following extensive study, Chen et al. suggested that these two peaks are due to turns, random structures, or a combination thereof. SFG polarization analysis showed that their behaviors were very different from those of $\alpha$-helical structures.

SFG signals were dominated by contributions from $\beta$-sheet structure. ($^{61}$)

**$\beta$-turns and Random Structure** After the DTT treatment for tachyplesin, the SFG bands at 1645 and 1664 cm$^{-1}$ remained. Following extensive study, Chen et al. suggested that these two peaks are due to turns, random structures, or a combination thereof. ($^{63,64}$) SFG polarization analysis showed that their behaviors were very different from those of $\alpha$-helical structures.

**3.3.4.3 Determination of $\alpha$-helical structure orientation** SFG has been widely used to determine orientation of functional groups on surfaces and at interfaces using polarization analysis, which has mostly been focused on C–H groups such as methyl and phenyl groups. ($^{18–20}$)

Chen et al. recently extended this analysis to analyze SFG amide I signals using a group theory projection operator method to correlate SFG polarization measurements to $\alpha$-helical structure orientation. ($^{53}$) There are two SFG-active amide I bands for $\alpha$-helical structure, $A$ and $E_2$ modes. Their SFG measurables $\chi_{xyz}$ are related to their hyperpolarizability tensor elements $\beta_{abc}$ through orientation as follows:

**A mode**:

$$
\chi_{A,xxx} = \chi_{A,yyz} = 1/2N_s[(1 + r)(\cos \theta) - (1 - r)(\cos^3 \theta)]\beta_{ccc}
$$

$$
\chi_{A,xzx} = \chi_{A,zyy} = \chi_{A,zzx} = \chi_{A,zzy} = 1/2N_s[(1 - r)(\cos \theta - (\cos^3 \theta))\beta_{ccc}
$$

$$
\chi_{A,zzz} = N_s[r(\cos \theta) + (1 - r)(\cos^3 \theta)]\beta_{ccc}
$$

where

$$
r = \beta_{abc}/\beta_{ccc}
$$

**E$_1$ mode**:

$$
\chi_{E,xxx} = \chi_{E,yyz} = -N_s[(\cos \theta - (\cos^3 \theta)]\beta_{aca}
$$

$$
\chi_{E,xzx} = \chi_{E,zyy} = \chi_{E,zzx} = \chi_{E,zzy} = N_s[(\cos^3 \theta)]\beta_{aca}
$$

$$
\chi_{E,zzz} = 2N_s[(\cos \theta) - (\cos^3 \theta)]\beta_{aca}
$$

Here $N_s$ is the surface density of $\alpha$-helical repeat units. Since the SFG hyperpolarizability can be deduced from Raman and IR properties of the $\alpha$-helical molecule, Chen et al. deduced the relations among different hyperpolarizability tensor elements to be $r = 0.54$ and $\beta_{aca} = 0.32\beta_{ccc}$ from experimental measurements of polarized Raman and IR. ($^{66–69}$) The detailed analysis indicated that only two SFG measurables regarding orientation angle $\theta$ were independent: $\langle \cos \theta \rangle$ and $\langle \cos^3 \theta \rangle$. Using different polarization combinations of the input and output laser beams, $\langle \cos \theta \rangle$ and $\langle \cos^3 \theta \rangle$ could be deduced. If it is assumed that all the $\alpha$-helical structures on the surface/interface adopt the same orientation, then $\langle \cos \theta \rangle$ and $\langle \cos^3 \theta \rangle$ can be replaced by $\cos \theta$ and $\cos^3 \theta$. Subsequently, the relationship between an SFG measurable and the orientation angle of the $\alpha$-helix can be depicted.

**3.3.4.4 Orientation Distribution of $\alpha$-helical Coiled-coils in Fibrinogen at Interfaces: Combined Sum Frequency Generation and Attenuated Total Reflection Fourier Transform Infrared Spectroscopy Studies** It might not be accurate to assume all the $\alpha$-helical structures on a surface/interface to have the same orientation. In these cases, a distribution function should be employed. As discussed above, lacking preliminary information regarding such an orientation distribution, the maximum
entropic function is the best trial function. Chen et al. studied orientation distribution of two \( \alpha \)-helical coiled-coils of fibrinogen at the PS/fibrinogen solution interface.

Figure 25(a) shows a schematic of the native fibrinogen structure, which (roughly) possesses inversion symmetry. Therefore, if fibrinogen adopted the native structure after adsorption to a surface (Figure 25b, c), little or no SFG signal would be detected. Experimentally, very strong SFG signal was detected from the PS/fibrinogen solution interface (Figure 25d), showing that adsorbed fibrinogen molecules do not adopt the native structure. The SFG signal was dominated by a peak centered at 1650 cm\(^{-1}\), which was mainly contributed by the \( \alpha \)-helical coiled-coils. SFG polarization analysis confirmed that this 1650 cm\(^{-1}\) peak was dominated by contributions from \( \alpha \)-helical structures. Chen et al. also used the NLOPredict software package from the Simpson group (Purdue University) to determine that fibrinogen domains other than coiled-coils did not contribute noticeable SFG \( \alpha \)-helix signals. The observed strong coiled-coil SFG signal indicated that fibrinogen adopted a bent structure after adsorption (Figure 25e, f).

Figure 26(a) shows the bent fibrinogen structure and orientation distribution of coiled-coils deduced by assuming that all the fibrinogen molecules have the same orientation (a \( \delta \) distribution), using the SFG intensity ratio measured with different polarization combinations of the input/output laser beams. Certainly such a distribution is unlikely because the polymer surface can be very complicated and thus induce different orientations or conformations of the fibrinogen molecules adsorbed. Figure 26(b, c) orientation distributions of coiled-coils deduced by two (b) and three (c) measurements. (Reproduced with permission from Ref. 55. Copyright 2007, American Chemical Society.)
c) shows the orientation distributions of α-helical coiled-coils of fibrinogen adsorbed on PS deduced using two SFG measurements (assuming a Gaussian distribution) and using combined SFG and ATR-FTIR (maximum entropy distribution) method, respectively.\(^\text{(55)}\)
The two distributions are similar, showing that the Gaussian distribution was a good assumption. However, the two distributions are not identical, showing that a combination of vibrational spectroscopic techniques should deduce the real distribution more accurately. The calculated distribution was quite broad, indicating that adsorbed fibrinogen molecules can adopt a variety of orientations and conformations. Using only ATR-FTIR to study such orientation, as is currently common, would reveal only one measured orientation angle, 52°, which is far from the real picture where coiled-coils adopted a very broad orientation distribution. This research demonstrated the importance of using multiple independent measurements to study orientation of α-helices.

### 3.3.4.5 Studies of α-helical Structures in Lipid Bilayers

Chen et al. also studied peptides in supported single lipid bilayers using SFG. It has been extensively shown that solid-supported lipid bilayers are valid models for cell membranes.\(^\text{(70)}\) SFG was applied to investigate structures of such lipid bilayers.\(^\text{(71–73)}\) For most of the research on supported lipid bilayers, glass, mica, and fused silica were used as solid substrates. Such surfaces can be negatively charged, which may induce interactions with peptides in the lipid bilayer, causing artifacts in the determination of peptide orientation in the bilayer. Chen et al. successfully constructed lipid bilayers on a variety of solid substrates such as SiO\(_2\), CaF\(_2\), and various polymers. It was found that the structure and stability of lipid bilayers on these substrates are identical to those on glass, mica, or fused silica.

**Melittin in Membrane**  It has been shown that melittin adopts α-helical structure in the lipid bilayer by a variety of analytical methods, but the orientation of melittin in a lipid bilayer is still controversial.\(^\text{(70,74,75)}\) Chen et al. first collected polarized ATR-FTIR spectra from melittin in a substrate-supported single lipid bilayer. This generates only one measured parameter: the intensity ratio of the s- and p-polarized ATR-FTIR absorbance. According to the ATR-FTIR results, the average orientation angle is 53.8° versus the surface normal.\(^\text{(76)}\) The SFG spectra from melittin in a lipid bilayer (Figure 27) were then collected. Both spectra shown in Figure 27 can be exclusively fitted by a single peak centered at 1650 cm\(^{-1}\), indicating α-helical structure. Using the SFG intensity ratio-orientation results, Chen et al. found that the SFG experimental data cannot be fitted using a δ-distribution or a Gaussian distribution (Figure 28).

![Figure 27](image.png)

**Figure 27** SFG amide I spectra collected from melittin adsorbed onto a 1,2-Dipalmitoyl-sn-Glycero-3-[Phospho-rac-(1-glycerol)] (DPPG)-supported bilayer at ssp and ppp polarization combinations. A solution concentration of 0.78 mM is used (arbitrary unit). (Reproduced with permission from Ref. 76. Copyright 2007, American Chemical Society.)

![Figure 28](image.png)

**Figure 28** $|X_{zzz}/X_{yyz}|$ ratio as a function of orientation angle, assuming a δ-distribution or Gaussian distribution function. Shaded area represents the actual experimental result. (Reproduced with permission from Ref. 76. Copyright 2007, American Chemical Society.)

If it is assumed that melittin can adopt two orientations, then combined SFG and ATR-FTIR results showed that the two orientation angles were $\theta_1 = 13^\circ$ and $\theta_2 = 100^\circ$ and coverages were $N_1 = 0.274$ and $N_2 = 0.726$, respectively (Figure 29a). These results were quite different from previous ATR-FTIR measurements, which suggested that these peptides were either perpendicular or parallel to the membrane surface. Chen et al. suggest that both orientations coexist.\(^\text{(76)}\) Such a result should be
more reliable, because more measurements were used to derive the result.

Without assuming a two-δ distribution function as above, a similar result can be obtained by using a maximum entropy function as the trial orientation distribution. As mentioned, mathematically it can be shown that with limited measurements the maximum entropy function introduces the least bias. The deduced result using the maximum entropy trial function is shown in Figure 29(b). The distribution function in Figure 29(b) is similar to that shown in Figure 29(a) with two preferred orientations (Figure 30), but without initial assumptions. This also suggests that for a protein with two (or even three) α-helical segments, the above method can be used to deduce their orientations.

**G Protein Associated with Membrane**  
Heterotrimeric guanine nucleotide-binding proteins (G proteins) are involved in numerous signal transduction pathways. Heterotrimeric G protein comprises three subunits, Gα, Gβ, and Gγ, with Gβ and Gγ forming a tightly associated dimer. Chen et al. studied the orientation of Gβγ in the lipid bilayer using SFG. Two types of Gβγ unit were used in this research: one with and relay the extracellular signals sensed by G protein–coupled receptors (GPCRs) to downstream effectors. A heterotrimeric G protein comprises three subunits, Gα, Gβ, and Gγ, with Gβ and Gγ forming a tightly associated dimer. Chen et al. studied the orientation of Gβγ in the lipid bilayer using SFG. Two types of Gβγ unit were used in this research: one with
geranylgeranyl anchor group and the other without. The SFG spectra collected from these two types of G\(\beta\gamma\) subunits were very different (Figure 31). The SFG spectra collected from the G\(\beta\gamma\) unit with the geranylgeranyl group associated with the lipid bilayer had much stronger signal intensities, even when a much lower protein concentration was used. The SFG signal was dominated by a peak at around 1650 cm\(^{-1}\), characteristic of contributions from \(\alpha\)-helical components. Chen et al. suggested that the geranylgeranyl anchor group was inserted into the lipid bilayer and thus G\(\beta\gamma\) units associated with the lipid bilayer adopted the same orientation, as shown in Figure 32(a). The \(\beta\)-sheet segments in this orientation did not contribute to SFG signals substantially because they have centrosymmetry, but the \(\alpha\)-helices generated strong SFG signals centered at 1650 cm\(^{-1}\) because of the ordered orientation. The SFG intensities in the spectra collected from the G\(\beta\gamma\) unit without the geranylgeranyl group associated with lipid bilayer were much weaker even though a much higher protein solution concentration was used. Chen et al. suggested that there were no specific interactions between the G\(\beta\gamma\) and the bilayer without the presence of the geranylgeranyl anchor. In this case, the SFG signal is dominated by the contributions from the \(\beta\)-sheet structure (Figure 32b), centered around 1630 cm\(^{-1}\). This indicates that it is necessary to have the anchor group on G\(\beta\gamma\) to ensure the specific orientation associated with the membrane.

Figure 32  Schematic of G\(\beta\gamma\) adsorbed onto a POPG/POPG bilayer deduced from the SFG spectra shown in Figure 31: (a) geranylgeranylated G\(\beta\gamma\) and (b) G\(\beta\gamma\) with no geranylgeranyl group. (Reproduced with permission from Ref. 79. Copyright 2007, American Chemical Society.)

Figure 33  SFG spectra collected from G\(\beta\gamma\) associated with different lipid bilayers: POPC:POPC; POPC:(POPC:POPG mixture); and POPC:POPG. The weaker signal in each panel is collected using ssp polarization combination and stronger one using ppp. Intensity ratios of ssp and ppp SFG signals are varied in different lipid bilayers, indicating that G\(\beta\gamma\) adopts different orientations. The orientation of G\(\beta\gamma\) in the POPC:POPC bilayer is shown in the upper left corner (Reproduced with permission from Ref. 79. Copyright 2007, American Chemical Society.)
The SFG spectra were also collected from Gβγ in lipid bilayers with different compositions (Figure 33): All three bilayers had an inner leaflet of 1-Palmitoyl-2-Oleoyl-sn-Glycero-3-Phosphocholine (POPC), while the outer leaflets that contacted Gβγ were varied as follows: POPG, POPG/POPC 1:1 mixture, and POPC. The SFG ppp/ssp spectral intensity ratios of Gβγ associated with various lipid bilayers were different, showing that Gβγ adopted different orientations owing to different lipid–protein interactions. The Gβγ orientation associated with the POPC:POPC bilayer was deduced and is shown in the upper left corner of Figure 33.

4 CONCLUSION

In conclusion, SFG vibrational spectroscopy is a powerful submonolayer-sensitive surface-specific analytical technique that provides a vibrational spectrum of surface functional groups on a centrosymmetric medium. SFG can provide both chemical specificity and orientation information. It has been applied to the study of a wide variety of systems, including complicated molecules such as polymers, proteins, peptides, and lipids at interfaces.

Terahertz spectroscopy has attracted great interest in recent years due to the development of improved terahertz radiation sources and terahertz radiation detectors as well as novel terahertz spectroscopy systems. This article discusses Fourier transform far-infrared spectroscopy, backward-wave oscillator terahertz spectroscopy, and time-domain terahertz spectroscopy. Terahertz spectroscopy is spectroscopy with electromagnetic radiation in the terahertz (THz) frequency range. THz radiation is invisible. The THz frequency range is located between microwaves and the infrared. THz spectroscopy measures the dielectric properties of liquid and solid as well as inorganic and organic materials in the THz frequency range. Furthermore, THz spectroscopy is a method for vibrational and rotational spectroscopy of gases.

Specifications and merits of Far-infrared Fourier transform spectroscopy, backward-wave oscillator terahertz spectroscopy, and time-domain terahertz spectroscopy for applications in analytical chemistry are compared. The frequency range, frequency resolution, and dynamic range of each method are discussed. Various measurement modalities such as transmission and reflection spectroscopy, phase-sensitive spectroscopy, and time-resolved THz spectroscopy are explained. The physical measurement principle of each method is discussed. The relationship between the measurement observed and the dielectric function of a material are presented for each method. Technical descriptions of the methods are provided. An overview on specific applications of THz spectroscopy is presented.

1 INTRODUCTION

Terahertz spectroscopy describes spectroscopy with electromagnetic radiation in the THz frequency range. The THz frequency range is located between the microwave and the infrared frequency range. Previously, this part of the electromagnetic wave spectrum was also referred to as the submillimeter or the far-infrared (FIR) frequency range. Correspondingly, submillimeter wave spectroscopy and FIR spectroscopy are synonyms of THz spectroscopy. A frequency of 1 THz corresponds to a wavelength of 300 µm, a wavenumber of 33 cm⁻¹, or energy of 4.1 meV. Terahertz spectroscopy measures the dielectric properties of materials. The method provides information on characteristic dynamical properties of materials in the gaseous, liquid, and solid state that occur on picoseconds to femtoseconds timescales. Terahertz spectroscopy is used to identify molecules in the gaseous state via characteristic rotational and vibrational absorption lines. Materials that form periodic molecules can be identified by THz spectroscopy through their phonon-absorption bands in the THz frequency range. Liquids and disordered solid materials generally show broad absorption bands at THz frequencies. However, in this case, it is possible to distinguish between different materials using THz spectroscopy based on dielectric contrast.

Terahertz spectroscopy has a long and successful tradition. The first observation of the rotation spectrum of HCL was published in 1925. Since then, the development of THz spectroscopy and its applications in analytical chemistry has been driven by improvements in THz radiation sources, THz radiation detectors, and THz spectrometers. Accordingly, different approaches to THz spectroscopy have been developed. Earlier, THz spectroscopy was performed with grating spectrometers. This approach was followed by two-beam interferometric spectrometers. These types of THz spectrometers rely on thermal radiation sources and THz detectors such as Golay cells, bolometers, photoconductors, or pyroelectric devices. The invention of coherent THz radiation sources such as backward-wave oscillators (BWOs), FIR molecular gas lasers, and THz quantum cascade lasers resulted in the development of THz spectrometers. A recent development in THz spectroscopy is time-domain (TD) THz spectroscopy. This method employs very short

pulses ($\leq 10^{-12}$ s) for broadband spectroscopy in the 0.1–3 THz frequency range. The THz radiation pulses are generated using femtosecond near-infrared (NIR) laser pulses incident on semiconductors or nonlinear optical crystals.\(^{21,22}\) The THz radiation pulses are detected using photoconducting antennas or electrooptic sampling.\(^{23–26}\) Time-domain THz spectroscopy measures the complex dielectric function of a material with high dynamic range.\(^{27}\)

All methods of THz spectroscopy discussed so far have in common that the material to be analyzed is illuminated with THz radiation from a THz radiation source. Another approach to THz spectroscopy is the detection and spectral analysis of THz radiation naturally emitted by a material. This type of THz spectroscopy is used as an experimental method in astronomy. It is performed with THz heterodyne spectrometers.\(^{28}\)

Today, commercially available THz spectrometers for analytical chemistry are far-infrared Fourier transform spectrometers (FIR-FTS), BWO THz spectrometers, and TD THz spectrometers. The specifications and performance of these three methods are discussed in the subsequent text.

2 SPECIFICATIONS AND PERFORMANCE OF DIFFERENT METHODS OF THz SPECTROSCOPY

2.1 Performance

In analytical chemistry, the important specifications for THz spectroscopy are the frequency range, the frequency resolution, and the dynamic range of measurement. The dynamic range is defined as the ratio of the largest to the smallest change in transmission (or reflection) that can be detected by a measurement, and is generally a function of frequency. The values of the dynamic range quoted in this article refer to maximum performance. Also, this article specifies the performance of commercially available THz spectrometers.

The performances of FIR-FTS, BWO THz spectrometers, and TD THz spectrometers differ by frequency range, frequency resolution, dynamic range, and absolute THz radiation power (Table 1). The frequency ranges of the different methods are also illustrated in Figure 3. A BWO THz spectrometer covers the 0.035–1.4 THz frequency range, whereas that of a TD THz spectrometer extends from 0.030 to 3 THz. The frequency range of operation of a BWO THz spectrometer strongly overlaps with that of a TD THz spectrometer. The FIR-FTS spectrometer starts operating at 0.3 THz. The frequency range of this type of instrumentation extends into the infrared part of the electromagnetic spectrum.

The difference in performance between BWO THz spectroscopy and TD THz spectroscopy are frequency

resolution and dynamic range. BWO THz spectroscopy allows measurements with 1–10 MHz resolution, whereas the frequency resolution of TD THz spectroscopy is restricted to 1–10 GHz. The dynamic range of TD THz spectroscopy is $10^8 : 1$, whereas that of a BWO spectrometer is $10^5 : 1$.

The frequency range of FIR-FTS starts at 0.3 THz and extends into the midinfrared and NIR (30–300 THz) range. The frequency resolution of FIR-FTS is 1–10 GHz. It is similar to the frequency resolution of TD THz spectroscopy but is lower than that of BWO THz spectroscopy. The dynamic range of FIR-FTS is much lower than that of BWO THz spectroscopy and TD THz spectroscopy.\(^\text{29}\)

In summary, the frequency range of BWO THz spectroscopy and TD THz spectroscopy is very similar. BWO THz spectroscopy is the method of choice for analytical chemistry if spectroscopy with megahertz frequency resolution is desired. TD THz spectroscopy is selected for a spectroscopic measurement if it is necessary to measure very small changes in transmission (or reflection) but megahertz frequency resolution is not needed. The dynamic range of a FIR-FTS below a few THz is low compared with that of BWO THz spectroscopy and TD THz spectroscopy. The strength of an FIR-FTS is that it permits broadband spectroscopy from the THz frequency range into the infrared.

### 2.2 Merits

All three approaches to THz spectroscopy discussed in this article (Table 2) permit measurements in transmission and reflection geometry. BWO THz spectroscopy and TD THz spectroscopy are phase-sensitive methods of spectroscopy. FIR-FTS is a non-phase sensitive measurement method. Phase-sensitive spectroscopy allows the measurement of the real and imaginary part of the dielectric function of a material. Non-phase sensitive spectroscopy measures only the absorption coefficient of a material. TD THz spectroscopy also allows time-resolved spectroscopy with picoseconds to femtoseconds resolution.

In THz transmission spectroscopy, the THz radiation is incident perpendicular onto the surface of the sample (Figure 4a). Part of the THz radiation beam is reflected from the sample surface and part of it is transmitted through the sample. In THz transmission spectroscopy, the THz radiation transmitted through the sample is recorded by the detector. In THz reflection spectroscopy, the angle of incidence onto the sample is off from the sample surface normal. The THz radiation beam

The complex index of refraction is related to the complex dielectric function \( \varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega) \) and the complex conductivity \( \sigma(\omega) = \sigma_1(\omega) + i\sigma_2(\omega) \) by the following relationships:

\[
\varepsilon = n^2, \quad \varepsilon_1 = n_0^2 - k_0^2, \quad \varepsilon_2 = 2n_0k_0.
\]

The power absorption coefficient \( \alpha \) of a material as defined by the Bouguer–Lambert law of transmission \( I_1 \propto I_0 \exp(-\alpha d) \) is calculated using \( k_0 \) and \( \alpha = 4\pi\kappa_0/\lambda \), where \( \lambda = c/\omega \) is the wavelength of the THz radiation. TD THz spectroscopy is phase sensitive because a single transmission or reflection measurement provides both the real and imaginary part of the complex index of refraction.

It is possible to perform time-resolved THz spectroscopy with femtoseconds to picoseconds temporal resolution using TD THz spectroscopy. The THz radiation pulses in a TD THz spectrometer are generated using a femtosecond NIR laser pulse. The femtosecond NIR laser beam is divided by a beam splitter on a pump beam, which excites the THz radiation pulse, and a probe beam that gates the THz detector. The temporal profile of the THz radiation pulse transmitted through

\[
t(\omega) = \frac{4n\exp\left(-\sqrt{\omega}c/nd\right)}{(n+1)^2 \left(1 - \left(\frac{n-1}{n+1}\right)^2 \exp\left[-2i\omega c/nd\right]\right)},
\]

\[
r_p(\Theta, n(\omega)) = -\frac{n^2(\omega) \cos\Theta - \sqrt{n^2(\omega) - \sin^2\Theta}}{n^2(\omega) \cos\Theta + \sqrt{n^2(\omega) - \sin^2\Theta}}
\]

\[
r_s(\Theta, n(\omega)) = -\frac{\cos\Theta - \sqrt{n^2(\omega) - \sin^2\Theta}}{\cos\Theta + \sqrt{n^2(\omega) - \sin^2\Theta}}
\]

In Equations (1)--(3), \( d \) is the sample thickness, \( c = 3 \times 10^8 \text{ m s}^{-1} \) is the velocity of light, \( \omega = 2\pi f \) is the angular frequency with \( f \) being the frequency, and \( \Theta \) is the angle of incidence. Furthermore, \( r_p \) and \( r_s \) are the reflections in the case of the incident THz electric field being polarized parallel (p) or perpendicular (s) to the plane of incidence. These equations apply for a homogenous sample with parallel front and back surfaces, which are embedded in air. Similar equations have been developed for samples consisting of multiple layers of different materials and a thin conducting layer on a transparent substrate. The complex index of refraction \( n \) of the sample is obtained from the measured transmission \( t \) and reflection \( r \) by numerically solving Equations (1)--(3). Computational routines have been developed for this purpose. The complex index of refraction is related to the complex dielectric function \( \varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega) \) and the complex conductivity \( \sigma(\omega) = \sigma_1(\omega) + i\sigma_2(\omega) \) by the following relationships:

\[
\varepsilon = n^2, \quad \varepsilon_1 = n_0^2 - k_0^2, \quad \varepsilon_2 = 2n_0k_0.
\]

The power absorption coefficient \( \alpha \) of a material as defined by the Bouguer–Lambert law of transmission \( I_1 \propto I_0 \exp(-\alpha d) \) is calculated using \( k_0 \) and \( \alpha = 4\pi\kappa_0/\lambda \), where \( \lambda = c/\omega \) is the wavelength of the THz radiation. TD THz spectroscopy is phase sensitive because a single transmission or reflection measurement provides both the real and imaginary part of the complex index of refraction.
TERAHERTZ SPECTROSCOPY

Figure 5 Schematic of experimental arrangements of time-domain THz spectroscopy and optical pump/THz probe spectroscopy.

(or reflected) from the sample is recorded by delaying the probe beam relative to the pump beam by an optical delay line. In optical pump/THz probe spectroscopy, the femtosecond NIR laser beam is divided into three beams: the pump beam for THz pulse generation, the probe beam for gating of the THz detector, and the optical pump beam. The optical pump beam is also incident on the sample surface and is aligned such that the optical beam focus and THz beam focus overlap. Absorption of the femtosecond NIR laser pulse by the sample drives the sample out of equilibrium. The return of the sample to equilibrium is probed by the THz radiation beam by delaying it relative to the femtosecond NIR pulse. This results in time-resolved THz spectroscopy with femtosecond-to-picosecond resolution and provides insight into the dynamic dielectric properties of a material (Figure 5).

BWO THz spectroscopy measures the transmissivity $T$ or reflectivity $R$ of the sample under investigation.\(^{[17,32]}\) The principle of BWO THz spectroscopy is multiple-beam interference. This is achieved because of multiple reflections of the continuous-wave THz radiation beam within the plane–parallel front and back surfaces of the sample. For transparent samples, the multiple-beam interference results in transmissivity and reflectivity of the sample changing periodically as a function of the THz frequency. The period of the oscillations is directly related to the index of refraction $n_0$ of the material by $m\lambda/2 = n_0 d$, where $\lambda$ is the THz radiation wavelength, $m$ is the number of interference maxima, and $d$ is the sample thickness (Figure 6). The absorption of the material determines the minima in the interference pattern. Low absorption is indicated by low minima. The general relationship between transmissivity $T$ or reflectivity $R$ of the sample and the index of refraction $n_0$ and attenuation coefficient $k_0$ is described by Equations (4), (5), and (6).\(^{[17]}\)

\[
T = \exp\left(-\frac{4\pi k_0 d}{\lambda}\right) \frac{(1 - R)^2 + 4R \sin^2 \psi}{\left(1 - \exp\left(-\frac{4\pi k_0 d}{\lambda}\right)\right)^2 + 4R \exp\left(-\frac{4\pi k_0 d}{\lambda}\right) \sin^2 \left(\frac{2\pi n_0 d}{\lambda} + \psi\right)}
\]

\[
R = \frac{(n_0 - 1)^2 + k_0^2}{(n_0 + 1)^2 + k_0^2}
\]

\[
\psi = \arctan\left(\frac{2k_0}{n_0^2 + k_0^2 - 1}\right)
\]

The index of refraction $n_0$ and attenuation coefficient $k_0$ of the sample are obtained by fitting Equations (4)–(6) to the measured transmissivity.

In the case of strong absorption of the sample, the interference maxima and minima are less pronounced (Figure 7). In this situation, it is necessary to measure, in addition to the transmissivity $T$, the phase delay $\Phi$ of the THz radiation transmitted through the sample.

\[
\Phi = \frac{2\pi n d}{\lambda} - \arctan\frac{k_0(n_0^2 + k_0^2 - 1)}{(k_0^2 + n_0^2)(2 + n_0)n_0}
\]

\[
+ \arctan\frac{R \exp\left(-\frac{4\pi k_0 d}{\lambda}\right) \sin\left(2\left(\frac{2\pi n d}{\lambda} + \psi\right)\right)}{1 - R \exp\left(-\frac{4\pi k_0 d}{\lambda}\right) \cos\left(2\left(\frac{2\pi n d}{\lambda} + \psi\right)\right)}
\]

The index of refraction $n_0$ and attenuation coefficient $k_0$ are obtained by fitting Equations (4)–(7) to the measurements of $T$ and $\Phi$.

BWO THz spectroscopy and TD THz spectroscopy are both phase-sensitive methods of THz spectroscopy. They measure the real and imaginary part of the dielectric function of the sample. Because TD THz spectroscopy measures transmission (or reflection), the complex index of refraction of a material is obtained...
from two measurements for transparent as well as strongly absorbing materials. In contrast, BWO THz spectroscopy, which measures transmissivity (or reflectivity), requires four measurements to obtain the complex index of refraction for strongly absorbing materials. Moreover, BWO THz spectroscopy measures only the static dielectric properties of a material. An advantage of a continuous-wave BWO THz spectrometer is that this instrument provides high frequency resolution and high dynamic range simultaneously. For a TD THz spectrometer, the dynamic range of the measurement decreases drastically with subgigahertz frequency resolution. The dynamic range and the frequency resolution are linked in TD THz spectroscopy due to the pulsed nature of the radiation and the TD measurement approach.

FIR-FTS also measures the transmissivity (or reflectivity) of a sample under investigation.\textsuperscript{11,12,14,15} The principle of FIR-FTS is two-beam interference of broadband THz radiation (Figure 8). Generally, FIR-FTS is performed with a Michelson interferometer and relies on Fourier transformation between the space and frequency domain. It measures the Fourier transform $I(s)$ of the transmission (or reflection) spectrum of a sample as a function of the spatial delay $s$ between two interfering beams, as described in Equation (8). In this equation, $k = 2\pi / \lambda$ is the wavenumber, $I$ is the total intensity of the broadband THz radiation source, and $I(k)$ is the intensity of the THz radiation in the wavenumber interval $\Delta k$, as described in Equation (9). The actual transmission (or reflection) spectrum of the sample is obtained by numerically calculating the inverse Fourier transform $I(s)$ of the measurement $I(k)$. The relationship between spectrum $I(k)$ and measured Fourier transform $I(s)$ is described in Equation (10).\textsuperscript{33}

\begin{equation}
I(s) = \frac{1}{2} I + \frac{1}{4} \int_{-\infty}^{\infty} I(k) \exp(iks) \, dk
\end{equation}

\begin{equation}
I = \frac{1}{2} \int_{-\infty}^{\infty} I(k) \, dk
\end{equation}

\begin{equation}
I(k) = \frac{2}{\pi} \int_{-\infty}^{\infty} \left\{ I(s) - \frac{1}{2} I \right\} \exp(-iks) \, ds
\end{equation}

The transmission (or reflection) spectrum measured by FIR-FTS provides information on the absorption frequencies, the relative strength of an absorption line, and the linewidth of the absorption. The absorption coefficient $\alpha$ of the material is obtained by using the Bouguer–Lambert law $I_s \propto I_0 \exp(-\alpha d)$ and measuring the transmission spectrum of two samples with different thickness $d$. FIR-FTS measures the static absorption coefficient of a material. Since FIR-FTS is non-phase sensitive, it does not provide information on the index of refraction of the material. In order to obtain the index of refraction of a material by FIR-FTS, it is necessary to measure the transmission and reflection spectrum of a sample. Another approach for obtaining the index of refraction is performing a Kramers–Kronig analysis of the measured absorption coefficient. However, the accuracy of this computational method requires measurements...
of the absorption coefficient over a wide range of frequencies.

The advantage of TD THz and BWO THz spectroscopy over FIR-FTS is the capability of phase-sensitive measurements that allows the direct determination of the index of refraction and attenuation coefficient of materials in the 0.02–3 THz frequency range. The advantage of FIR-FTS is the rapid determination of absorption lines, their relative strength, and linewidth over a wide frequency range of 0.3–300 THz.

TD THz spectroscopy is performed in the time-domain and FIR-FTS spectroscopy is performed in the space domain. Both methods rely on frequency multiplexing, which describes that all frequencies represented in the broadband THz radiation source are incident on the sample simultaneously. For both methods, frequency demultiplexing is performed by Fourier transformation of the measurement to the frequency domain. BWO THz spectroscopy is performed in the frequency domain. The spectrum is recorded by continuously changing the emission frequency of the BWO THz radiation source. The advantage of a BWO-tunable THz radiation source in comparison to a FIR-FTS is that frequencies less than 1 THz are beyond the useful measurement range of most FIR-FTS. The much higher brightness of the BWO THz radiation source results in a much larger signal-to-noise ratio at frequencies below 1.4 THz.

3 TECHNICAL DESCRIPTIONS

3.1 Far-infrared Fourier Transform Spectrometer

Fourier transform spectroscopy is a method used for spectroscopies in the FIR (THz) and ultraviolet frequency range. The basic components of a Fourier transform spectrometer are a broadband THz radiation source, a two-beam (Michelson) interferometer, and a broadband detector (Figure 8). The components are selected according to the frequency range of operation. In the FIR (0.3–20 THz), the radiation source of choice is a globar. Sensitive detectors for FIR radiation are silicon bolometers cooled to temperatures between 1.4 and 4 K. The beam splitters for the interferometer are made from Mylar. Optics used to focus the FIR radiation onto the sample is made from polyethylene or polypropylene.

The globar emits a broad spectrum of FIR radiation. A beam splitter divides the FIR radiation beam into two. One of the beams is reflected from a fixed mirror, whereas the other is reflected from a movable mirror. The path difference between the two beams is changed by moving the mirror. The beam splitter combines the two beams again and steers the FIR radiation to the detector. FIR-FTS measures the interferogram \( I(s) \) of the two FIR radiation beams as a function of the path difference between the two beams. The spectrum \( I(k) \) is obtained through calculation of the Fourier transform of the interferogram \( I(s) \). For spectroscopy, the FIR radiation beam is focused onto a sample and the transmitted (or reflected) FIR radiation is detected. The illustration in Figure 8 is only a schematic of FIR-FTS. Various versions of two-beam interferometers for specific applications of FIR-FTS have been developed and are described in the literature.\(^{14}\)

3.2 Backward-wave Oscillator Terahertz Spectrometer

The THz radiation source in a BWO THz spectrometer is a BWO,\(^ {17} \) which is an electron beam device. A cathode produces electrons via thermal emission. Subsequently, electrons are accelerated by applying high voltage toward an anode. An applied magnetic field focuses the electrons to a narrow beam. The electron beam interacts with a periodic metallic structure while traveling to the anode. Electromagnetic interactions between the electron beam and the metallic periodic structure result in the generation of THz radiation. The THz radiation is collected by a waveguide and coupled to free space by a horn antenna. The frequency of the THz radiation is determined by the electron velocity, which in turn depends on the applied accelerating voltage. The frequency of THz radiation emitted by a BWO is tunable. Continuous tuning of the THz radiation frequency is achieved by changing the applied voltage. The frequencies of typical BWOs are listed in Table 3. The THz radiation power of a BWO can be as high as 50 mW. The THz radiation power is characterized by high frequency stability \( \Delta f/\nu = 10^{-5} \).
Figure 9  Schematics of a phase-sensitive BWO THz spectrometer.

high long-term power stability \( \Delta P/P = 10^{-3} \), and high degree of linear polarization (100 : 1).

Phase-sensitive THz transmission and reflection spectroscopy with BWOs as the THz radiation source is illustrated in Figure 9. In transmission geometry, the THz radiation emitted by the BWO is collected by a lens and split into two beams by a wire-grid beam splitter. One beam is transmitted through the material to be analyzed and the second beam serves as a reference to measure the phase shift induced on the transmitted THz radiation wave by the material. The transmitted beam and the reference beam are combined by a second wire grid and focused on the detector. Depending on whether transmission or reflection measurements are performed, the measured quantities are the transmission coefficient \( T \) of the sample and the phase shift \( \Phi_t \) of the transmitted wave or reflection coefficient \( R \) and phase shift \( \Phi_r \) of the reflected beam. These measured quantities are directly related to the complex dielectric function \( \varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega) \) and complex magnetic permeability \( \mu(\omega) = \mu_1(\omega) + i\mu_2(\omega) \) of the material under investigation. For nonmagnetic materials, the two unknown quantities \( \varepsilon_1 \) and \( \varepsilon_2 \) are obtained from either a transmission or a reflection measurement. For magnetic materials, four unknown quantities have to be determined, \( \varepsilon_1, \varepsilon_2, \mu_1, \) and \( \mu_2 \), using the measured transmission and reflection coefficient and corresponding phase shifts.\(^{32}\)

### 3.3 Time-domain Terahertz Spectrometer

A TD THz transmission spectrometer is powered by a femtosecond NIR laser and operates according to the pump–probe principle.\(^{23,24,26}\) A schematic of the experimental arrangements is displayed in Figure 5. The pump–probe principle is briefly described as follows: The femtosecond NIR laser beam is split into two beams. One of the beams, the pump beam, hits the THz radiation source, which in response to the femtosecond laser pulse releases a pulse of THz radiation. The probe beam gates the THz detector whose response is proportional to the amplitude and the sign of the electric field of the THz pulse. The time profile of the THz pulse is traced by varying the time delay between the pump and probe beam. An example of a measured THz radiation pulse is illustrated in Figure 10. In this experiment, the THz radiation pulse traveled approximately 0.3 m through air with a residual water vapor concentration of \( 1.7 \times 10^{-3} \) kg m\(^{-3}\). The Fourier transform of the THz radiation pulse is illustrated in Figure 11. The frequency spectrum extends from 0.45 to 2.5 THz. The Fourier transform shows that the dynamic range of the TD THz spectrometer is a function of frequency. The maximum of the dynamic range for measurements of the THz electric field is 800 : 1 at 0.3 THz. The spectrum in Figure 11 is the THz spectrum of air with a residual water vapor concentration of \( 1.7 \times 10^{-3} \) kg m\(^{-3}\). In comparison, Figure 12 displays the spectrum of a THz radiation pulse, which traveled the same distance but through air with a residual water vapor
Fourier amplitude (arb unit) vs. Frequency (THz) for Figure 11 and Figure 12.

Figure 11  Spectrum of the THz radiation pulse. It is obtained by Fourier transformation of the time-domain measurement of the THz radiation pulse to the frequency domain. In this measurement, the THz radiation pulse propagated through 0.3 m of nitrogen (N$_2$) with a residual water vapor concentration of $1.7 \times 10^{-3}$ kg m$^{-3}$ at room temperature and atmospheric pressure. The dynamic range of the TD THz spectrometer is frequency dependent. The maximum of the dynamic range is at $\sim 0.3$ THz.

Figure 12  Spectrum of another THz radiation pulse. Again, it is obtained by Fourier transformation of the time-domain measurement of the THz radiation pulse. In this measurement, the THz radiation pulse propagated through 0.3 m of nitrogen (N$_2$) with a residual water vapor concentration of $6.9 \times 10^{-3}$ kg m$^{-3}$ at room temperature and atmospheric pressure. The sharp dips in the spectrum correspond to water vapor absorptions lines in the THz frequency range.

3.3.1 THz Radiation Emitters for Time-domain THz Spectrometers

THz radiation sources used in TD THz spectrometers are either semiconductors or nonlinear optical crystals. Terahertz radiation emission from semiconductors exposed to femtosecond NIR laser pulses originates either from a nonlinear optical process or from ultrafast photocurrents. Nonlinear optical processes resulting in THz radiation emission are bulk- or surface-field-induced optical rectification of the incident femtosecond NIR laser pulses. Generation of THz radiation pulses due to optical rectification of femtosecond laser pulses either in a semiconductor or in a nonlinear optical crystal is based on difference in frequency mixing of all frequencies within the bandwidth $\Delta f$ of a femtosecond NIR laser pulse.$^{(26)}$ Terahertz radiation emission due to ultrafast photocurrents can be achieved through acceleration of photocarriers by intrinsic or extrinsic electric fields.$^{(23,24)}$ Intrinsic electric fields occurring at a semiconductor surface are surface depletion/accumulation electric fields or a photo-Dember field. Extrinsic electric fields are generated by applying laterally a voltage across a gap between two metal electrodes deposited on the semiconductor surface (photoconductive switch).

3.3.2 THz Radiation Detectors for Time-domain THz Spectrometers

The THz radiation detector in a TD THz spectrometer is either a photoconducting antenna or an electrooptic THz detector. A photoconducting antenna for the detection of the temporal waveform of THz radiation pulses consists of a thin-film antenna deposited on a thin semiconductor layer supported by an electrically insulating substrate, which is transparent at THz frequencies.$^{(23,24)}$ The semiconductor layer is manipulated such that it exhibits a high-dark resistivity and femtosecond carrier lifetime. Most commonly, ion-implanted silicon-on-sapphire (SOS) or low-temperature-grown GaAs (LT-GaAs) on semi-insulating GaAs is used for detector fabrication. The thin-film antenna is typically a center-fed dipole, which is approximately 50 $\mu$m long and 10 $\mu$m wide or a bipolar dipole antenna with 30- $\mu$m separation. Both types of antenna have a 5- $\mu$m-wide photoconducting gap in the center. A schematic of the experimental arrangements for photoconducting detection is displayed in Figure 13. For the detection, the femtosecond laser probe beam and the THz beam incident perpendicular onto the antenna from opposite sides. The probe beam is focused onto the photoconducting gap of the antenna. The THz radiation is incident through the substrate onto the antenna. The THz radiation is focused by a parabolic mirror and the coupling of the THz radiation to the substrate is enhanced by a small high-resistivity silicon lens that is attached to the substrate. The electrical field of the incident THz radiation couples to the antenna and induces a voltage across the photoconducting gap. A photocurrent $j(t)$ flows under the action of the induced voltage when the probe
laser beam excites photocarriers in the photoconducting gap. This photocurrent is the convolution of the transient conductivity $\sigma(t)$ of the semiconductor and the electric field $E(t)$ across the photoconducting gap, as described in Equation (11). The magnitude and sign of the current $j(t)$ are proportional to the amplitude and phase of the electric THz field $E(t)$. The current is measured by a current amplifier.

$$ j(t) = \int \sigma(t - t') E(t') \, dt' $$

The temporal profile of the THz radiation pulse is measured by scanning the femtosecond laser pulse through the THz pulse by an optical delay line.

An alternative to photoconducting antennas for the measurement of the temporal waveform of a THz radiation pulse is electrooptic detection.\(^{25,26}\) Electrooptic detection of THz radiation pulses relies on the fact that the electric field of a THz radiation beam, which passes through a nonlinear optical crystal such as a ZnTe crystal, induces birefringence in the crystal via the Pockel’s effect.\(^{34}\) This birefringence can be probed by a linearly polarized femtosecond laser pulse, which propagates collinearly with the THz beam through the ZnTe crystal. The phase difference $\Delta \Phi$ between the ordinary and extraordinary ray of the probe laser pulse is directly proportional to the electric THz field. In Equation (12), $\omega_{\text{opt}}$ is the angular frequency of the probe laser beam, $n_0$ is the index of refraction of the ZnTe crystal, $r_{41}$ is the electrooptic coefficient of ZnTe, and $\Delta x$ is the thickness of the ZnTe crystal.

$$ \Delta \Phi = \frac{\omega_{\text{opt}}}{c} n_0 r_{41} E_{\text{THz}} \Delta x $$

**Figure 13** Detection of THz radiation with photoconducting antennas in a TD THz spectrometer.

**Figure 14** Detection of THz radiation in a TD THz spectrometer by electrooptic sampling.
The experimental arrangements for electrooptic detection are displayed in Figure 14. The setup consists of a λ/2 plate, a Glan–Thomson polarizer, a pellicle beam splitter, a ZnTe crystal, a λ/4 plate, a Wollaston prism, and two photodiodes. Collinear propagation of the probe beam and of the THz beam in the ZnTe crystal is achieved through the pellicle beam splitter. The pellicle beam splitter is transparent for THz radiation but reflects optical light. The λ/2 plate allows a variation in the plane of polarization of the linearly polarized optical laser beam. The Glan–Thomson prism enhances the degree of linear polarization from 100 : 1 at the output of the Ti-sapphire laser to 10⁶ : 1.

The induced birefringence of the ZnTe crystal changes the linear polarization of the optical probe pulse to elliptical polarization. Subsequently, the elliptical polarization is changed into a circular polarization by the λ/4 wave plate. The Wollaston prism spatially separates the two orthogonal components of the circularly polarized laser light. Finally, the intensity of each orthogonal component is individually detected by a photodiode. The difference in the photodiode output is measured by a lock-in amplifier. The THz electric field is proportional to the difference in the output of the two photodiodes. The temporal profile of the THz radiation pulse is measured again by scanning the femtosecond laser pulse through the THz radiation pulse.

### 3.3.3 Optics for Time-domain THz Spectrometers

The THz radiation is collected, steered, and focused with gold-plated off-axis parabolic mirrors. The mirrors have a typical diameter of 25–50 mm. The focal length of the mirrors is typically 25–300 mm. In order to achieve proper THz beam steering, it is important that the THz emitter, sample, and THz detector are accurately positioned at the focal points of the mirrors to avoid spatial transformations of the THz beams. As a result of spatial transformations, phase changes and frequency filtering of the pulse time profile may occur.³⁵

### 4 OVERVIEW OF APPLICATIONS OF THz SPECTROSCOPY

Traditional areas of application of THz spectroscopy have been chemistry, materials science, and physics. A large body of work on THz spectroscopy of gases, liquids, and solids has been reported.³³,⁴,⁷,⁸,³⁸–³⁹ It is beyond the scope of this article to survey and summarize all this work.

As explained previously, FIR spectroscopy is a synonym of THz spectroscopy. Therefore, THZ spectroscopy is infrared spectroscopy in the very low frequency range of the infrared (Figure 1). THz spectroscopy measures the dielectric function of materials in the THz frequency range. The dielectric function provides information on the dynamic properties of a material. All selection rules for infrared spectroscopy also apply to THz spectroscopy.

A very fruitful area of research has been THz spectroscopy of gases. Small polar molecules in the gas phase exhibit characteristic absorption lines in the microwave frequency range (Figure 1) and THz frequency range. The absorption frequencies of diatomic molecules with a permanent electric dipole moment are

\[ f = \frac{2h}{(8\pi^2 I)(j + 1)} \]

where \( j = 0, 2, 3, \ldots \), \( h = 6.6 \times 10^{-34} \) Js, the moment of inertia is \( I = \mu r^2 \), the internuclear distance is \( r \), and \( \mu = m_1m_2/(m_1 + m_2) \) the reduced mass of the molecule. Absorption due to excitation of rotations occurs for molecules with a small reduced mass \( \mu \). Examples are HF, HCl, H₂O, and NH₃. The vibration frequency of diatomic molecules is

\[ \omega = 2\pi f = (k/\mu)^{1/2} \]

where \( k \) is the force constant of the bond and \( \mu \) is the reduced mass of the molecules. Vibrational frequencies of molecules are found in the THz frequency range for a large reduced mass (at least one heavy atom) or a weak force constant. Examples of weak force constants are atoms bound by hydrogen or van der Waals bonds. Examples of molecules with a large reduced mass are heavy-metal-to-metal or metal-to-ligand bonds.³³

The understanding of rotational and vibrational transitions of molecules in the THz frequency range is important for the understanding of the transmission of the atmosphere in this frequency range.³⁸,³⁹

THz spectroscopy of biomolecules and pharmaceutical applications of THz spectroscopy are emerging as new areas of application.⁴⁰–⁴² A combination of THz spectroscopy and THz imaging is suggested as a novel medical imaging modality.⁴³

Theory of Infrared Spectroscopy

George Turrell
Université des Sciences et Technologies de Lille,
Lille, France

1 Introduction

This article is devoted to the fundamentals of infrared spectroscopy. While it is well known that infrared spectroscopy is an extremely important analytical technique, its theoretical basis is not easily assimilated by most analytical chemists. It must be admitted that a certain understanding of abstract concepts, such as those encountered in quantum mechanics, is required. However, with all apologies to the reader, it is the objective here to present the essentials of these ideas, as needed in analytical applications of infrared spectroscopy. It should be noted that most of these principles apply equally to Raman spectroscopy, a subject which is described in other articles.

It is the Born–Oppenheimer approximation that provides the theoretical basis for the analysis of infrared spectra. The rotational and vibrational degrees of freedom of a molecule are specified to allow the spectra of molecules in the gas phase to be interpreted. It is shown that the logical extension of these arguments can be employed in the analysis of the spectra of liquids and crystalline solids.

In later sections, an effort has been made to explain how the basic ideas developed earlier can be applied to the interpretation of the infrared spectra of hydrogen-bonded molecules, polymers and amorphous systems. A brief description of the notion of characteristic group frequencies, as routinely employed in organic chemistry, has been included to allow the practicing chemist to appreciate the possibilities – as well as the limitations – of this most important approach to the subject. To advance his appreciation of the advantages of infrared spectroscopy in analytical chemistry, the reader should refer to the various applications, as listed at the end of this article.

1 INTRODUCTION

The theoretical basis of the infrared spectroscopy of molecular systems is established by the analysis of the dynamics of the nuclear displacements. The Born–Oppenheimer approximation is of course the fundamental argument in the treatment of this problem. As the masses of the electrons and the nuclei in a molecule are significantly different, the much lighter electrons
move rapidly to create the so-called electron cloud which “sticks” the nuclei into relatively fixed equilibrium positions. The resulting geometry of the nuclear configuration is usually referred to as the molecular structure. It will be shown in this article that this molecular geometry plays an essential role in the determination of the vibrational and rotational spectra, both infrared and Raman, of a given molecule.

The analytical application of infrared spectroscopy can without doubt be founded on the work of Coblentz. His early publication, which has been reprinted, represents the most important contribution to the development of analytical applications of infrared spectroscopy. However, the more practical or “routine” use of infrared spectroscopy as an analytical tool had to await the evolution of the necessary instrumentation, for a large part the result of military requirements during World War II. Thus, after a half century the early observations by Coblentz were confirmed and applied to what is now the field of analytical infrared spectroscopy. Initial applications were for the most part limited to the mid-infrared region, from 4000 to approximately 500 cm⁻¹, by the instrumentation available. However, it is just this region that yields spectral features that can be identified, at least approximately, with organic functional groups. Furthermore, it is this region that is important in the analysis of molecular vibrations, as it is here that most vibrational fundamentals are observed. With the introduction of matrix methods, followed by the development of digital computers, the calculation of molecular force fields from observed vibrational spectra became possible. These results have provided invaluable information concerning the nature of the chemical bond.

The objective of this article is to summarize the theoretical basis of this important area of analytical chemistry. It must be admitted that the mathematical treatment of certain aspects can become rather demanding. An effort will be made to reduce these difficulties to a minimum, to allow the practicing analytical spectrocopist to appreciate the bases of the theoretical problem, without being obliged to delve into the mathematical details.

2 THE DIATOMIC MOLECULE

2.1 Kinetic Energy

The vibrational and rotational motions of a free diatomic molecule, as in an ideal gas, can be simply represented by the displacement of two point masses \( m_1 \) and \( m_2 \) in free space. The kinetic energy of the two-particle system is then given in Cartesian coordinates by Equation (1):

\[
T = \frac{1}{2}[m_1(x_1^2 + y_1^2 + z_1^2) + m_2(x_2^2 + y_2^2 + z_2^2)]
\]  

The introduction of the reduced mass \( \mu \), defined by Equation (2):

\[
\frac{1}{\mu} = \frac{1}{m_1} + \frac{1}{m_2}
\]  

allows the kinetic energy to be expressed as a function of the relative positions of the two particles. Furthermore, if the spherical coordinates \( r, \theta, \phi \) with respect to the center of mass are employed to describe the position of a hypothetical particle of mass \( \mu \), the Schrödinger equation for this system becomes (Equation 3):

\[
-\frac{\hbar^2}{8\pi^2\mu} \frac{1}{r^2} \frac{\partial}{\partial r} \left( r^2 \frac{\partial}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left( \sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2}{\partial \phi^2} \psi + V(r) \psi = E \psi
\]

where \( h \) is Planck’s constant. The usual procedure for the separation of independent variables can then be made by the introduction of Equation (4):

\[
\psi(r, \theta, \phi) = R(r)Y(\theta, \phi)
\]

The functions \( Y(\theta, \phi) \) are the well-known spherical harmonics. The resulting expression for the \( r \)-dependent function is then of the following form (Equation 5):

\[
-\frac{\hbar^2}{8\pi^2\mu r^2} \frac{d}{dr} \left( r^2 \frac{d}{dr} \right) + \frac{\hbar^2 J(J + 1)}{8\mu r^2} + V(r) \ R(r) = E R(r)
\]

It is important to note that the second term in brackets contains the factor \( J(J + 1) \), which arises from the boundary conditions imposed on the spherical harmonics. The requirement that \( J = 0, 1, 2, 3, \ldots \), has the effect of quantizing the angular momentum associated with the rotation of the diatomic molecule. Clearly, the solutions to Equation (5) depend on the form of the potential function which, in this case, governs the interaction between the two nuclei. The rotation of the system, which produces the centrifugal force, contributes the energy given by the second term in Equation (5). Thus, the square of the angular momentum is quantized according to Equation (6):

\[
\mathcal{J}^2 = \frac{\hbar^2}{4\pi^2} J(J + 1)
\]

(see section 3.8).

To take the simplest case, suppose that the distance between the two masses is held constant, \( r = r_c \). Then, as \( V(r) = 0 \), Equation (5) reduces to Equation (7):

\[
E_{\text{rot}} = \frac{\hbar^2 J(J + 1)}{8\pi^2\mu r_c^2}
\]
where $E_{\text{rot}}$ is the energy of the rigid rotor. This approximation is usually the first step in the interpretation of the pure rotational spectra of diatomic molecules, as observed in the microwave and far-infrared regions.

### 2.2 Potential Energy

According to the Born–Oppenheimer approximation, the effect of the electron cloud is to produce an interaction potential of the form shown by the solid curve in Figure 1. Although a number of empirical functions exist to represent this function, as a first approach, the harmonic approximation is employed. Here, the development of the potential function $V(r)$ is carried out in a Taylor series in the following form (Equation 8):

$$V(r) = V_0 + \frac{dV}{dr} (r-r_e) + \frac{1}{2} \left( \frac{d^2V}{dr^2} \right) (r-r_e)^2 + \cdots$$

As the origin of the potential energy scale is arbitrary, $V_0$ can be chosen equal to zero. The second term in Equation (8) vanishes, because the slope of the curve at the minimum, $r = r_e$, is of course zero. The first nonvanishing term is thus the quadratic term in $x = r - r_e$. In the harmonic approximation higher terms in this development are neglected and the potential function becomes (Equation 9)

$$V(r) = \frac{1}{2} f (r-r_e)^2 = \frac{1}{2} fx^2$$

where the force constant $f$ can be identified with the curvature of the potential function at the minimum.

The solution to the one-dimensional Schrödinger equation with the potential function given by Equation (9) leads to wave functions expressed as Hermite polynomials and the energy in the following form (Equation 10):

$$E_{\text{vib}} = \hbar \nu_c (v + \frac{1}{2})$$

where $v = 0, 1, 2, \ldots$ is the vibrational quantum number. The quantity $\nu_c = (1/2\pi) \sqrt{f/\mu}$ is equal to the vibrational frequency of the corresponding classical oscillator.$^{(2)}$

### 2.3 Rigid Rotating Harmonic Oscillator

With the rotational energy given by Equation (7) and the vibrational energy given by Equation (10), the total energy takes the simple form of Equation (11):

$$E_{J,v} = E_{\text{rot}} + E_{\text{vib}} = \frac{\hbar^2 J(J+1)}{8 \pi^2 \mu r_e^2} + \hbar \nu_c (v + \frac{1}{2})$$

The practicing spectroscopist usually writes this expression as Equation (12):

$$\frac{E_{J,v}}{\hbar c} = \tilde{\nu}_c \left( v + \frac{1}{2} \right) + \tilde{\beta}_e J(J+1)$$

where $\tilde{\beta}_e$ is the rotational constant expressed in cm$^{-1}$ and $\tilde{\nu}_c$ is the vibrational wavenumber, often referred to (incorrectly) as the vibrational “frequency”. Equation (11) is represented by the energy-level diagram presented in Figure 2. The figure is not to scale, as the relative separation between the fundamental vibrational levels $v = 0$ and those of the excited state $v = 1$ is usually much greater than indicated.

A first approximation to the calculation of the rotation–vibration spectrum of a diatomic molecule can be made on the basis of Figure 2. It is sufficient to impose the selection rules $\Delta v = 1$ for vibrational absorption
and $\Delta J = \pm 1$ for the accompanying rotational transitions, as shown. It is important to note that there is no transition that corresponds to the purely vibrational frequency, as the rotational transition $\Delta J = 0$ is forbidden by the rotational selection rules. This analysis indicates that the fundamental transition $v = 0 \Rightarrow v = 1$ should yield a series of equally spaced lines, with a missing element at the center, where $\Delta J = 0$ (see section 5.1).

### 2.4 Vibrating Rotator

The simple description presented above of the rotation–vibration spectrum of a diatomic molecule was based on the rigid rotator–harmonic oscillator approximation. However, if Equation (12) is generalized to include the anharmonicity of the vibration, in addition to the effects of centrifugal distortion and rotation–vibration coupling, it becomes (Equation 13)

$$
\frac{E_{J,v}}{\hbar c} = \tilde{v}_e \left( v + \frac{1}{2} + \tilde{B}_e J(J+1) - \tilde{v}_e x_e \left( v + \frac{1}{2} \right)^2 - D_J J^2 (J+1)^2 - \tilde{a}_e \left( v + \frac{1}{2} \right) J(J+1) \right) \tag{13}
$$

The various parameters appearing in Equation (13) can be evaluated from the rotation–vibration spectra of diatomic molecules or with the use of an empirical function to represent the curve shown in Figure 1. In the latter case, the Morse function (Equation 14)

$$
V(r) = D_e \left[ 1 - e^{-a(r-r_e)} \right]^2 \tag{14}
$$

which is one of the simplest, usually yields satisfactory results. In Equation (14) $D_e$ is the energy of dissociation and the parameter $a$ is $\sqrt{1/2D_e}$.

### 3 POLYATOMIC MOLECULES

Within the framework of the Born–Oppenheimer approximation the electronic energy of a molecule is considered to be a function of its instantaneous nuclear configuration. What is often referred to as the “electronic problem” is then the solution of the Schrödinger equation for the movement of the electrons for each fixed configuration of the $N$ atoms in the molecule. The values of the energy as functions of the molecular configuration represent the effective potential function that governs the movement of the nuclei. The solutions to this problem yield the various possible values of the energy $E_{\text{nucl}}$ for each electronic state of the molecule.

This energy, associated with the movement of the nuclei, is usually decomposed, at least in a first approximation, in the following form (Equation 15):

$$
E_{\text{nucl}} = E_{\text{trans}} + E_{\text{rot}} + E_{\text{vib}} + \text{interactions} \tag{15}
$$

The interaction terms are not always negligible, although in analytical applications of vibrational spectroscopy it is usually an acceptable approximation. Furthermore, the translational contribution to the energy is in most cases classical. In other words, it does not have spectroscopic significance. In the case of solids, however – particularly at low frequencies – its effects should not be overlooked.

The conclusions of the above arguments are that for practical purposes the energy of an isolated molecule can be expressed as the sum of two terms, corresponding to its rotational and vibrational energies. This approximation is the initial step in the interpretation of the spectra of gases, as summarized in section 5. The rotation of molecules in condensed phases is restricted by the intermolecular forces. Thus, as a first approximation, the infrared and Raman spectra of liquids and solids can be analyzed with the consideration of only the vibrational energy of the system. However, the intermolecular forces often have important consequences, as they determine to a large extent the shapes of vibrational bands and are responsible for “solvent effects” in the spectra of solutions. These questions are considered later.

### 3.1 Vibrational Kinetic Energy

The vibrational energy of an isolated molecule will now be written as the sum of the kinetic and potential energies (Equation 16):

$$
E_{\text{vib}} = T + V \tag{16}
$$

A set of $3N$ Cartesian displacement coordinates in the following form (Equation 17):

$$
\begin{align*}
\Delta x_1 \\
\Delta y_1 \\
\Delta z_1 \\
\vdots \\
\Delta x_2 \\
\Delta y_2 \\
\Delta z_2 \\
\vdots \\
\Delta x_N \\
\Delta y_N \\
\Delta z_N
\end{align*}
\tag{17}
$$

\[ \xi = \begin{array}{cccc}
\Delta z_2 \\
\vdots \\
\Delta x_N \\
\Delta y_N \\
\Delta z_N
\end{array} \]
can be employed to express the kinetic energy. If a diagonal matrix of the atomic masses is defined by Equation (18):

\[
M = \begin{pmatrix}
  m_1 & 0 & 0 \\
  0 & m_2 & 0 \\
  0 & 0 & m_N
\end{pmatrix}
\]  \quad (18)

the kinetic energy in terms of these matrices takes the compact form (Equation 19)

\[ T = \frac{1}{2} \dot{\xi}^T M \xi \]  \quad (19)

where the dot over the vector defined by Equation (17) indicates that the time derivative has been taken and the tilde represents the transpose operation.

3.2 Internal Coordinates

It is usually convenient to work with a set of internal displacement coordinates, \( S \), as they have chemical significance. In the limit of small amplitudes of atomic displacements, the two sets of coordinates are linearly related. Thus (Equation 20),

\[ S = B \xi \]  \quad (20)

where the matrix \( B \) is determined by the equilibrium geometry of the molecule. Equation (19) allows the kinetic energy to be expressed in internal coordinates as Equation (21):

\[ T = \frac{1}{2} \dot{S}^T G^{-1} \dot{S} \]  \quad (21)

where the matrix \( G \) is defined by \( G \equiv BM^{-1}B \). Although, in principle, the \( G \) matrix can be constructed with a knowledge of the atomic masses and the molecular geometry, tables of its elements are available that were developed many years ago.\(^{(3)}\) In present-day computer programs, it is constructed and employed directly to calculate the vibrational frequencies and the specific forms of the normal modes of vibration, as summarized in the following sections.

3.3 Potential Energy

Although the equilibrium configuration of a molecule can usually be specified, at ordinary temperatures all of the atoms undergo oscillatory motions. The forces between the atoms in the molecule are described by a Taylor series of the intramolecular potential function in the internal coordinates. This function can then be written in the following form (Equation 22):

\[ V = \frac{1}{2} \sum_{i,r} \left( \frac{\partial^2 V}{\partial S_i \partial S_r} \right)_0 S_i S_r = \frac{1}{2} \sum_{i,r} f_{i,r} S_i S_r \]  \quad (22)

an expression that includes the first nonzero terms in the expansion of the potential function with respect to the equilibrium configuration. Clearly, Equation (22) is a generalization of the harmonic potential for the diatomic molecule (Equation 9). Although higher terms in this series can be added to take into account the anharmonicity of the molecular vibrations, the harmonic approximation is employed in most practical calculations of the vibrational frequencies of a polyatomic molecule. Equation (22) can be written in matrix form as Equation (23):

\[ V = \frac{1}{2} F S S \]  \quad (23)

where \( F \) is a symmetric matrix of the force constants. Although the force constants can in principle be calculated from the molecular electronic wave functions, the results are not yet quantitatively reliable. These quantities are usually treated as variable parameters in the vibrational problem. Their evaluation from experimental spectroscopic data is of importance, both as a means of testing the results of ab initio electronic calculations and for their chemical significance. For example, the knowledge of the value of a force constant associated with the stretching of a chemical bond provides some insight into the nature of the bond, including semiquantitative measures of both its length and its dissociation energy.

3.4 Normal Coordinates

It is now fundamental to define the normal coordinates of this vibrational system – that is to say, the nuclear displacements in a polyatomic molecule. Again in the limit of small amplitudes of vibration, the normal coordinates in the form of the vector \( Q \) are related to the internal coordinates by a linear transformation, viz. (Equation 24)

\[ S = L Q \]  \quad (24)

The kinetic and potential energies given by Equations (21) and (23) become (Equation 25)

\[ T = \frac{1}{2} \dot{S}^T G^{-1} \dot{S} = \frac{1}{2} \dot{Q}^T L G^{-1} L \dot{Q} = \frac{1}{2} \dot{Q} \dot{E} \dot{Q} \]  \quad (25)
respectively. The matrices $E$ and $\Lambda$ are both diagonal. The former is the unit matrix, while the latter is composed of elements $\lambda_k = 4\pi^2 v_k^2$. The vibrational frequencies are given by $v_k$, where the subscript $k$ identifies the normal mode of vibration. An inspection of Equations (25) and (26) identifies the role of the normal coordinates, namely, to eliminate simultaneously all cross-terms in the expressions for the kinetic and potential energies. This condition can be taken as the definition of the normal modes of vibration.

### 3.5 Secular Determinant

The last step in the calculation of the frequencies of molecular vibrations, as observed in the infrared spectra, is carried out by combining Equations (25) and (26). The vibrational energy of a polyatomic molecule is then given in this, the harmonic approximation, by Equation (27):

$$E_{\text{vib}} = T + V = \frac{1}{2} Q \hat{E} Q + \frac{1}{2} Q \hat{\Lambda} Q$$  
(27)

From Equations (25) and (26), it is apparent that $L G^{-1} L = E$ and $L F L = \Lambda$. With the definition of the $G$-matrix, $L = L^{-1} G$. Therefore (Equation 28),

$$L^{-1} G F L = \Lambda$$  
(28)

Hence, as is often stated, the determination of the normal coordinates is equivalent to the successful search for a matrix $L$ that diagonalizes the product $GF$ via a similarity transformation. This system of linear, simultaneous, homogeneous equations can be written in the following form (Equation 29):

$$\sum_r [(GF)_{rr} - \delta_{rr} \lambda_k] L_{rk} = 0$$  
(29)

where the Kronecker delta is defined by Equation (30):

$$\delta_{rr} = \begin{cases} 1, & \text{if } r = r' \\ 0, & \text{if } r \neq r' \end{cases}$$  
(30)

This set of equations for the elements of $L$ can be resolved by application of Cramer’s rule. Then, a nontrivial solution exists only if the determinant of the coefficients vanishes, or (Equation 31)

$$|GF - E \lambda_k| = 0$$  
(31)

This condition on the so-called secular determinant is the basis of the vibrational problem. The roots of Equation (31), $\lambda_k$, are the eigenvalues of the matrix product $GF$, while the columns of $L$, the eigenvectors, determine the forms of the normal modes of vibration. These relatively abstract relations become more evident with the consideration of an example.

### 3.6 The Water Molecule

As a simple illustration of the development of the secular determinant, consider the water molecule. A reasonable set of internal coordinates consists of the changes in lengths of the two bonds and the variation in the bond angle. Thus, from Equation (20) and Figure 3 (Equation 32)

$$S = \begin{pmatrix} \Delta r_1 \\ \Delta r_2 \\ \Delta \alpha \end{pmatrix} = B \xi$$

where $s = \sin \alpha/2$, $c = \cos \alpha/2$ ($\alpha$ being the equilibrium bond angle) and $r$ is the equilibrium $O-H$ bond length, as shown in Figure 3. The masses of the hydrogen and oxygen atoms are arranged according to Equation (18) in the order established by the vector $\xi$, namely (Equation 33),

$$M = \begin{pmatrix} m_H & m_H & 0 \\ m_H & m_H & 0 \\ 0 & m_O & m_O \end{pmatrix}$$

Figure 3 Internal coordinates for the water molecule.
The $G$ matrix, as calculated from its definition, becomes (Equation 34)
\[
G = BM^{-1}B
\]
where $\mu = 1/m_H$ and $\mu_O = 1/m_O$.

The force-constant matrix based on internal coordinates is of the following form (Equation 35):
\[
F = \begin{pmatrix} f_r & f_r & f_a \\ f_r & f_r & f_a \\ f_a & f_a & f_a \end{pmatrix}
\]
where $f_r$ is the coefficient of $(\Delta r_1)^2$ and $(\Delta r_2)^2$, and $f_a$ is the coefficient of $(\Delta a)^2$ in the potential energy expression. These constants are referred to as the principal or valence force constants. The off-diagonal constant $f_{ra}$ represents an interaction constant which is the coefficient of $(\Delta r_1 \Delta a_2)$ and $(\Delta r_2 \Delta a_1)$ in the potential energy expression, while the interaction constant $f_{aa}$ is the coefficient of all four terms of the type $(\Delta a_1 \Delta a_2)$. By taking the product of the above matrices $G$ and $F$, the secular equation in the form of Equation (31) can be readily found.

In the construction of the matrix $F$ of Equation (35), the symmetrical equivalence of the two O–H bonds was taken into account. Nevertheless, it contains four independent force constants. As the water molecule has only three fundamental vibrational frequencies, at least one interaction constant must be neglected or some other constraint introduced. If all of the off-diagonal elements of $F$ are neglected, the two principal constants, $f_r$ and $f_a$, constitute the valence force field (VFF) for this molecule. However, to reproduce the three observed vibrational frequencies this force field must be modified to include the interaction constant $f_{ra}$. This example will be reconsidered in section 4.7, after the question of molecule symmetry has been treated.

### 3.7 Molecular Rotation

The rotational energy of a molecule can be written in the following form (Equation 36):
\[
E_{\text{rot}} = \frac{1}{2} \mathbf{\omega}^T \mathbf{I} \mathbf{\omega}
\]
where it has been assumed that the molecule acts as a rigid rotator. In effect, in the limit of infinitesimal vibrational amplitudes, the moment of inertia tensor, $\mathbf{I}$, which becomes equal to that of a rigid rotator, is of the following form (Equation 37):
\[
\mathbf{I} = \begin{pmatrix} I_{xx} & I_{xy} & I_{xz} \\ I_{yx} & I_{yy} & I_{yz} \\ I_{zx} & I_{zy} & I_{zz} \end{pmatrix}
\]

The Cartesian coordinates employed in Equation (37) have been assumed to be attached to the rigid, rotating molecule. It should be noted that the moment of inertia tensor is symmetric with respect to the principal diagonal; thus, $I_{xy} = I_{yx}$, etc. The angular velocity associated with the rotation of the molecule is represented here by the vector $\mathbf{\omega}$. Equation (36) can then be written out in the following form (Equation 38):
\[
E_{\text{rot}} = \frac{1}{2} \mathbf{\omega}^T \mathbf{I} \mathbf{\omega} = \frac{1}{2} \left( \frac{2}{I_a} + \frac{2}{I_b} + \frac{2}{I_c} \right)
\]

It is in general possible to find a Cartesian coordinate system attached to the molecule such that the tensor $\mathbf{I}$ takes a diagonal form. In terms of these so-called principal axes Equation (38) is simplified in that all cross-terms are eliminated (Equation 39):
\[
E_{\text{rot}} = \frac{1}{2} (I_a w_a^2 + I_b w_b^2 + I_c w_c^2)
\]

The definition of the principal axes labeled $a$, $b$, $c$ is usually dictated by the symmetry properties of the molecule (see section 4.5).

### 3.8 Classification of Rotators

With the use of principal axes it becomes possible to classify the types of rotator as follows:
1. linear: $I_a = I_b \neq I_c = 0$
2. spherical: $I_a = I_b = I_c \neq 0$
3. symmetric: $I_a = I_b \neq I_c = 0$
4. asymmetric: $I_a \neq I_b \neq I_c$

Within the framework of the rigid-rotor approximation, it then becomes possible to express in closed form the energy of each of the first three types of rotator. From Equation (36) with the angular velocity given by $\mathbf{\omega} = \begin{pmatrix} w_a \\ w_b \\ w_c \end{pmatrix}$, the rotational energy can be written in the following form (Equation 40):
\[
E_{\text{rot}} = \frac{1}{2} \mathbf{\omega}^T \mathbf{I} \mathbf{\omega} = \frac{1}{2} \left( \frac{2}{I_a} + \frac{2}{I_b} + \frac{2}{I_c} \right)
\]

where $a$, $b$, and $c$ are the components of the angular momentum with respect to the principal axes $a$, $b$, and $c$, respectively.\(^{(3,4)}\)
In the quantum-mechanical treatment of the rotational problem, it is shown that the square of the total angular momentum is quantized, namely (Equation 41)

$$\mathcal{M}^2 = \frac{2}{a} + \frac{2}{b} + \frac{2}{c} = \frac{\hbar^2}{4\pi^2}J(J + 1)$$

(41)

where the rotational quantum number is defined by $J = 0, 1, 2, 3, \ldots$ (see section 2.1).

### 3.8.3 Symmetric Rotators

If $c$ is chosen as the unique axis of a linear molecule, $c = 0$ and the rotational energy is given by Equation (42):

$$E_{\text{rot}} = \frac{\hbar^2}{8\pi^2}J(J + 1)$$

(42)

where $I = I_a = I_b$ is the moment of inertia of the molecule. It should be noted that there is a degeneracy equal to $2J + 1$, as the quantum number $M = 0, \pm 1, \pm 2, \ldots, \pm J$.

### 3.8.2 Spherical Rotators

If the principal moments of inertia are equal, viz. $I = I_a = I_b = I_c$, Equation (36) leads to the same expression for the energy as given by Equation (42), i.e. (Equation 43)

$$E_{\text{rot}} = \frac{\hbar^2}{8\pi^2}J(J + 1)$$

(43)

where, as above, $I$ is the moment of inertia of the molecule at equilibrium. Then, as $\epsilon = (\hbar/2\pi)K$, where the additional quantum number $K = 0, \pm 1, \pm 2, \ldots, \pm J$, the resulting degeneracy is equal to $(2J + 1)^2$.

### 3.8.3 Symmetric Rotators

In this case the principal moments are related by $I = I_a = I_b \neq I_c \neq 0$, where again the $c$-axis has been chosen as the unique direction. The classical rotational energy can then be given as Equation (44):

$$E_{\text{rot}} = \frac{2}{2I_a} + \frac{2}{2I_b} + \frac{2}{2I_c} = \frac{\mathcal{M}^2}{2I_a} + \frac{2}{2}\left(\frac{1}{I_c} - \frac{1}{I_a}\right)$$

(44)

With the use of the relations given above, the quantum-mechanical expression becomes (Equation 45)

$$E_{\text{rot}} = \frac{\hbar^2}{8\pi^2}J(J + 1) + \frac{\hbar^2 K^2}{8\pi^2} \left(\frac{1}{I_c} - \frac{1}{I_a}\right)$$

(45)

Equation (45) allows two types of symmetric rotator to be defined. If $I_c < I_a$, the rotator is elongated in the direction of the $c$-axis. It is said to be a prolate top, as, say, an American football. The second term on the right-hand side of Equation (45) is then positive. On the other hand, if $I_c > I_a$, the rotator is flattened with respect to the $c$ direction, as the earth – or in the limit, a pancake. In this case the second term on the right-hand side of Equation (45) is negative and the rotator is an oblate top. These two types of rotator can usually be distinguished in their rotation–vibration spectra by the contribution of the second term. The degeneracy for this class of rotator is rather complicated, viz. $2J + 1$ if $K = 0$ and $2(2J + 1)$ if $|K| > 0$ (see section 5.3).

### 3.8.4 Asymmetric Rotators

In the most general case, all three principal moments of inertia are different: $I_a \neq I_b \neq I_c$. Unfortunately, most molecules fall into this class. No analytical expression can be written for the rotational energy of an asymmetric rotator. However, extensive tables for the energy levels were calculated many years ago. More recently, computer programs have been developed to carry out their numerical evaluation for a given molecular structure.

### 4 MOLECULAR SYMMETRY

Although all molecules are in constant thermal motion, when all of their atoms are in their equilibrium positions, a specific geometrical structure can usually be defined. The normal modes of vibration of such a structure, and hence an interpretation of its vibrational spectrum, can then be calculated – at least in the harmonic approximation.

#### 4.1 Symmetry Elements

The mathematical description of the structure of a molecule is based on an application of group theory. It is necessary, then, to define certain symmetry operations. Although there are various ways of specifying these operations, geometrical descriptions are certainly the easiest to understand. Each symmetry operation (aside from the trivial one, $E$, the identity) is associated with an element of symmetry. Thus, for example, certain molecules are said to be planar. Well-known examples are water, boron trifluoride and benzene, whose structures can be drawn in the forms shown in Figure 4(a–c).

(a) H        O        H
(b) F        B        F
(c) H        C        C        H

Figure 4 Planar molecules: (a) water; (b) boron trifluoride; (c) benzene.
The symmetry operations and their descriptions, and the notation established by Schönflies, are given in Table 1. To identify the symmetry group it is necessary to visualize all of the operations which characterize the structure of the molecule. As there is always at least one point in space that is not affected by any of these operations, the group is referred to as a point group. Usually with experience, and the aid of molecular models, the symmetry operations are not too difficult to find.

The molecules shown in Figure 4(a–c) are planar; thus, the paper on which they are drawn is an element of symmetry and the reflection of all points through the plane yields an equivalent (superposable) structure. The process of carrying out the reflection is referred to as the symmetry operation \( s \). However, as the atoms of these molecules are essentially point masses, the reflection operations result simply in the inversion of the direction (the coordinate) perpendicular to the plane.

In general, a molecule may have a number of elements of symmetry. For example, the water molecule has, in addition to the plane of symmetry indicated above, a second perpendicular to the first. The reflection operation with respect to this plane inverts the \( y \) direction, as well as interchanging the identification of the hydrogen atoms (see Figure 5).

The presence of two perpendicular planes of symmetry implies the existence of another element of symmetry, Table 1.

The number of independent symmetry operations in a group is called the order of the group.

4.2 Group Theory

Without entering into the mathematical details, it is important to point out that the ensemble of symmetry operations that characterizes the structure of a molecule forms a group.\(^5,6\) That is,

1. The combination of any two members of the ensemble is an element of the ensemble.
2. There is one element of the ensemble which permutes with all of the others and leaves them unchanged. It is known as the identity, \( E \) (German: Einheit).
3. The associative law of combination is valid.
4. Each element of the ensemble has an inverse that is also a member of the ensemble.

In (1), the combination of two members of the ensemble, that is, two symmetry operations, implies their successive application. It should be noted that in general these operations do not commute. The number of independent symmetry operations in a group is called the order of the group.
4.3 Coordinate Transformations

In the foregoing discussion, the symmetry operations have been described as “rotations”, “reflections”, etc. that is, as dynamic operations. However, strictly, symmetry operations are really coordinate transformations that modify the mathematical statement of the atomic positions, rather than the positions themselves. Furthermore, these transformations are subject to the condition that they cannot modify the potential energy of the molecule. This property follows from the fact that any coordinate system is merely a bookkeeping scheme without physical significance.

Returning to the water molecule as an example, the Cartesian displacement coordinates as given in Equation (32), are of the following form (Equation 46):

\[
\xi = \begin{pmatrix}
\Delta x_1 \\
\Delta y_1 \\
\Delta z_1 \\
\vdots \\
\Delta x_2 \\
\Delta y_2 \\
\Delta z_2 \\
\vdots \\
\Delta x_3 \\
\Delta y_3 \\
\Delta z_3
\end{pmatrix}
\]  

(46)

for this triatomic system. A symmetry operation \( R \) results in a coordinate transformation (Equation 47):

\[
\xi' = R\xi
\]

(47)

to form the vector \( \xi' \). Specifically, for the reflection \( R = \sigma(z,x) \) the matrix representation is given by Equation (48):

\[
R = \begin{pmatrix}
0 & 0 & 0 \\
0 & 0 & -1 \\
0 & -1 & 0 \\
0 & 1 & 0 \\
0 & 0 & 0 \\
0 & 0 & 0 \\
\end{pmatrix}
\]  

(48)

Thus, in this example it is apparent that in Equation (48) the submatrix associated with the oxygen atom remains along the diagonal, while those for the two equivalent hydrogen atoms are displaced.

It is perhaps not surprising that the specific form of a matrix representation, such as that given in Equation (48), depends on the chosen basis coordinates – in this case the elements of the vector \( \xi \). However, there is always one quantity that is invariant, namely the trace of the representation matrix, that is, the sum of its diagonal elements. In group theory it is known as the character, as it characterizes the representation.

Each submatrix \( R_i \) appearing in a representation such as \( R \) in the above example can be written in the following general form (Equation 49):

\[
R_i = \begin{pmatrix}
\cos \theta_j & -\sin \theta_j & 0 \\
\sin \theta_j & \cos \theta_j & 0 \\
0 & 0 & \pm 1
\end{pmatrix}
\]  

(49)

where \( \theta_j = 2\pi/n \) is the angle of (counterclockwise) rotation for a given symmetry operation (or class of symmetry operation), as given in Table 1. Then, for each atom \( i \) the contribution to the character of the representation is given by Equation (50):

\[
\text{Trace } R_i = (2\cos \theta_j \pm 1)
\]  

(50)

where in Equations (49) and (50) the positive sign is employed for the so-called proper operations \((E\) and \(C_n)\) and the negative sign for the improper ones \((\sigma, S_n\) and \(i)\). Clearly, for the example of the operation \(\sigma\), Equation (50) yields \(2\cos 0 - 1 = 1\) for the trace of the submatrix for the oxygen atom (see Equation 48). This result can be generalized to obtain the following expression for the character of the representation of any symmetry operation (Equation 51):

\[
\chi_j = m_j (2\cos \theta_j \pm 1)
\]  

(51)

where \( m_j \) is the number of atoms in the molecule that are not permuted by the symmetry operations of class \( j \). This relation, which is independent of any choice of basis coordinates, will be applied repeatedly in the following applications.

4.4 Irreducible Representations

As indicated above, there may be many – even an infinity – of matrix representations of a given symmetry operation, depending on the choice of basis coordinates. However, there exists a particular set of basis coordinates in terms of which the representation matrix is reduced to block-diagonal form. This result is shown symbolically in Figure 7. Each submatrix \( \Gamma^{(k)} \) is called an irreducible representation (IR), as there exist no
basis coordinates that can result in a further reduction. Here, for example, the arbitrarily chosen first IR occurs three times, the second once and the third once again. In this figure the smaller squares \((k = 1, 2)\) indicate one-dimensional matrices, while \(\Gamma^{(3)}\) is an IR of order two.

The result shown schematically in Figure 7 can be expressed mathematically in the following form (Equation 52):

\[
\Gamma = \sum_{\gamma} n^{(\gamma)} \Gamma^{(\gamma)}
\]

if it is understood that the summation is special. It indicates that the direct sum is to be diagonal, that is, the various IRs are arranged along the diagonal of the reduced representation. Each IR, identified by the superscript \((\gamma')\), may appear more than once, or not at all. Thus, \(n^{(\gamma)}\) is equal to the number of times that the IR \(\Gamma^{(\gamma)}\) appears in the reduced representation.

While it is not, in general, necessary to find the explicit forms of the IR matrices, their characters are readily available from standard tables. This information is sufficient for the resolution of most problems encountered in molecular spectroscopy.

### 4.5 Character Tables

The tables of the characters of the IRs have the general form shown in Table 2. For a point group the columns are headed by the symbols \(\gamma\), the classes of symmetry operation. Each class may be composed of one or more symmetry operations, although by tradition the arbitrarily chosen first class consists uniquely of the identity operation, \(E\). The rows are labeled by the identification of the IRs. In a given IR the operation \(E\) corresponds to a unit matrix whose order is equal to the dimension of the representation. Hence the resulting character is equal to the dimension of the representation and the dimension of each IR can be easily determined by inspection of the first column of characters in the table. It should be noted that the matrix of characters is square, that is, the number of IRs is equal to the number of classes of symmetry operation.

A further property of the character tables arises from the fact that every symmetry group has an IR that is invariant under all of the group operations. This IR is a one-by-one matrix composed of the number one for every class of operation. Obviously, the characters, are all then equal to one. As this IR is by convention taken to be \(\Gamma^{(1)}\), the first row of each character table consists solely of ones. The significance of the character tables will become more apparent by consideration of an example.

The water molecule in its equilibrium configuration is represented in Figure 5. The symmetry elements \(\sigma(2\chi)\) and \(\sigma(2\chi)\) are shown. The intersection of these two planes is the \(z\)-axis, which is collinear with the binary axis of symmetry, \(C_2\). The symmetry operations with respect to these elements, plus of course the identity \(E\), define the group \(C_2\) in the notation of Schönlies. It is then said that the water molecule “belongs” to the symmetry group \(C_{2v}\).

The water molecule has \(3N = 9\) degrees of freedom. Of these, three describe the position in space of the center of mass of the molecule, as specified by a vector with components \(T_x, T_y, T_z\). Similarly, the angular momentum vector associated with the rotation of the molecule, is identified by its components \(R_x, R_y, R_z\). These coordinates, which represent the six external degrees of freedom, are classified for molecules of \(2\) symmetry in Table 3.

The classification of rotators made in section 3.8 can now be reconsidered in terms of the symmetry elements defined in Table 1. If a molecule has one symmetry

axis of threefold or higher symmetry, it is a symmetric rotator. Two angular momentum components will appear together, e.g. \((R_x, R_y)\) in a doubly degenerate IR. If the molecule has two or more axes of greater than twofold symmetry, it is a spherical rotator, and all three components will be grouped in a three-dimensional IR. Clearly, the water molecule is an example of an asymmetric rotator.

4.6 Reduction of a Representation: The "Magic Formula"

The relation between a reducible representation and the IRs is given by Equation (52). In practical applications, it is essential to determine the values of \(n^{(j)}\), the number of times that each IR enters the direct sum shown in Figure 7. As \(X_j\) is merely the sum of the diagonal elements of \(\Gamma\) for each class of operation \(j\), it is also equal to the sum of the traces of the individual submatrices \(\Gamma^{(j)}\), each multiplied by \(n^{(j)}\). It follows that (Equation 53)

\[
X_j = \sum_{\gamma=1}^{k} n^{(\gamma)} x^{(\gamma)}_j \quad j = 1, 2, \ldots, k \tag{53}
\]

where \(x^{(\gamma)}_j\) is the character of the IR \(\Gamma^{(\gamma)}\) of an operation of the class \(j\). This set of simultaneous equations can be solved with aid of the orthogonality properties of the characters. The result is given by Equation (54):

\[
 n^{(j)} = \frac{1}{g} \sum_{\gamma=1}^{k} g_j x^{(\gamma)}_j X_j \tag{54}
\]

This expression is of such widespread applicability that it is often referred to as the "magic formula". In it, \(g\) is the order of the group, that is, the total number of independent symmetry operations. The characters for each class of operation \(x^{(\gamma)}_j\), are given in the character table for the symmetry group of the molecule, while \(x_j\) is the corresponding character of the reducible representation. The latter can be calculated, for example, from Equation (51). Each product in the summation appearing in Equation (54) is weighted by the quantity \(g_j\), the number of independent symmetry operations in each class\(^{(3,6)}\).

4.7 Examples

In spite of the apparent complexity of the magic formula, its application is fairly simple, as shown in the following examples. The water molecule was described above, where it was indicated that it is of symmetry \(2v\). The character table is presented in Table 3, where it is seen that the order of the group is equal to four and that each class is composed of only a single symmetry operation. The characters for the reducible representation, as calculated with the use of Equation (51), are shown in the last line of Table 3. Thus, Equation (54) yields the values of \(n^{(j)}\)(tot) given in the first column to the right of the character table. This result indicates that the symmetry of the \(3N\) degrees of freedom of the water molecule (or any triatomic molecule of symmetry \(2\nu\)) can be described by the direct sum \(\oplus\) of IRs (Equation 55):

\[
\Gamma = 3A_1 \oplus A_2 \oplus 2B_1 \oplus 3B_3 \tag{55}
\]

As indicated above, for the \(3N - 6\) normal vibrations of a nonlinear molecule in free space, the coordinates of translation and rotation can be removed. The symmetry of these external coordinates, \(T_x, T_y, T_z\) and \(R_x, R_y, R_z\), is given in each character table. The difference for this example, \(2A_1 \oplus B_2\), describes the symmetry of the three normal modes of vibration of the molecule. Two of them are symmetric with respect to all four of the symmetry operations of the point group. However, the mode of species \(B_2\) is antisymmetric under the operations \(C_2\) and \(\sigma(xz)\), as shown in Table 3.

As a second example, the symmetry elements of the ethane molecule in its staggered conformation are illustrated in Figure 6. The ensemble of 12 symmetry operations forms the group \(3d\), whose character table is presented in Table 4. Note that in this case the IRs \(E_g\) and \(E_u\) are doubly degenerate, as indicated by the number two in the column headed \(E\), the identity. The characters of the reducible representations are given in the last line. As in the previous example, the structure of the reduced representation is determined by the values of \(n^{(j)}\)(tot) determined by application of the magic formula. The removal of the external coordinates leads to the values of \(n^{(j)}\)(vib) shown in the last column. The values of \(n^{(j)}\)(vib) given for the doubly degenerate species are the number of pairs of normal modes. Thus, for example, there are three pairs of normal modes of symmetry \(E_u\), corresponding to three distinct vibrational frequencies. Note that the subscripts \(g\) and \(u\) (German: gerade, ungerade) specify the symmetry with respect to the inversion operation, as indicated in Table 4.

4.8 Symmetry Coordinates

The characters $\chi_j$ for the examples in the previous section were calculated with the use of Equation (51), that is, on the basis of Cartesian displacement coordinates. Alternatively, it is often desirable to employ a set of internal coordinates as the basis. However, they must be well chosen so that they are sufficient to describe the vibrational degrees of freedom of the molecule and that they are linearly independent. The latter condition is necessary to avoid the problem of redundancy. Even when properly chosen, the internal coordinates still do not usually transform following the symmetry of the molecule. Once again, the water molecule provides a very simple example of this problem.

The internal coordinates for the water molecule are defined in Figure 3. The effect of each symmetry operation of the symmetry group $\nu\gamma$ on these internal coordinates is specified in Table 5. Clearly, the internal coordinates of the internal coordinates is specified in Table 5. The effect of the operation of the symmetry group $\nu\gamma$ on these internal coordinates is specified in Table 5. The effect of the operation of the symmetry group $\nu\gamma$ on these internal coordinates is specified in Table 5. Clearly, the internal coordinates of the internal coordinates is specified in Table 5. The effect of the operation of the symmetry group $\nu\gamma$ on these internal coordinates is specified in Table 5.

From the above analysis, as shown in the last column of Table 5, it should be obvious that two linear combinations of the internal coordinates $\Delta r$ can be formed whose symmetry corresponds to the IRs $A_1$ and $B_2$. They are $\Delta r_1 + \Delta r_2 (A_1)$ and $\Delta r_1 - \Delta r_2 (B_2)$, as can be verified by inspection of the character table.

Co-existent coordinates such as these, which have the symmetry properties of the point group, are known as symmetry coordinates. As they transform in the same manner as the IRs when used as basis coordinates, they factor the secular determinant into block-diagonal form.\(^{(3)}\) Thus, while normal coordinates must be found to diagonalize the secular determinant, the factorization resulting from the use of symmetry coordinates often provides considerable simplification of the vibrational problem. Furthermore, symmetry coordinates can be chosen a priori by a simple analysis of the molecular structure.

In the example considered above, $\Delta r_1 - \Delta r_2$ is the only symmetry coordinate of species $B_2$. Thus, it results in a factor of degree one in the completely reduced secular determinant. It is therefore a normal coordinate. On the other hand, the two normal coordinates of species $A_1$ are linear combinations of the symmetry coordinates $\Delta r_1$ and $\Delta r_1 + \Delta r_2$. They can only be found by solution of the secular equations.

It is usually convenient to normalize the symmetry coordinates. Hence, for the example considered here, the three symmetry coordinates take the form (Equation 56)

$$S_1 = \Delta r_1 \quad S_2 = \frac{1}{\sqrt{2}} (\Delta r_1 + \Delta r_2) \quad (56)$$

and (Equation 57)

$$S_3 = \frac{1}{\sqrt{2}} (\Delta r_1 - \Delta r_2) \quad (57)$$

where the normalizing factor $p$ is determined by the condition (Equation 58)

$$p^2 \sum_i S_i^2 = 1 \quad (58)$$

for each symmetry coordinate $S_p$. In general form, the relations given by Equations (56) and (57) are expressed by the matrix relation (Equation 59)

$$S = US \quad (59)$$

which for the above example becomes (Equation 60)

$$\begin{pmatrix} S_1 \\ S_2 \\ S_3 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 \\ \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} & 0 \\ \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} & 0 \end{pmatrix} \begin{pmatrix} \Delta r_1 \\ \Delta r_2 \\ \Delta r_3 \end{pmatrix} \quad (60)$$

It should be noted that when the symmetry coordinates have been normalized, $U$ is orthogonal, that is, $U = U^{-1}$. The matrices $U$ can be constructed with the use of projection operators. For lack of space, this method will not be presented here.

To show how use is made of symmetry coordinates as the bases of the vibrational problem, reconsider the kinetic and potential energies as given earlier, e.g. (Equation 61)

$$2T = SG^{-1}S = QE\tilde{Q} \quad (61)$$

and (Equation 62)

$$2V = SFS = Q\Lambda Q \quad (62)$$

From Equation (59), we have (Equation 63)

$$S = U^{-1}S = US \quad (63)$$

$\chi_j (\Delta \alpha)$ \quad $\chi_j (\Delta r)$
hence (Equation 64)

\[ 2T = SG^{-1}S = \hat{Q}E\hat{Q} \quad (64) \]

and (Equation 65)

\[ 2V = SFS = \hat{Q}AQ \quad (65) \]

In Equations (64) and (65) the definitions \( G \equiv UGU \) and \( F \equiv UFU \) have been introduced. These equations lead to the secular determinant as before (Equation 66):

\[ |GF - E\lambda_k| = 0 \quad (66) \]

The eigenvectors \( L \) with this basis can be found from \( L = UL \).

Returning now to the example of the water molecule, with \( F \) given by Equation (35) and \( U \) in Equation (60), the transformation \( UFU \) gives Equation (67):

\[ F = \frac{f_a \sqrt{2f_{rr}}}{f_a + f_{rr}} \begin{pmatrix} 0 \\ \sqrt{2f_{rr}} \\ f_a + f_{rr} \\ 0 \\ f_a - f_{rr} \end{pmatrix} \quad (67) \]

Similarly, \( UGU \) leads to Equation (68):

\[ G = \begin{pmatrix} 2\mu_H/r^2 + 2\mu_O/2 & \mu_H + \mu_O/2 \\ \sqrt{2}\mu_O/2 & \mu_H + \mu_O/2 \end{pmatrix} \]

\[ \begin{pmatrix} 0 \\ \mu_H + \mu_O/2 \times (1 + \cos\alpha) \end{pmatrix} \]

(68)

As both \( F \) and \( G \) are partitioned by the use of symmetry coordinates, the secular determinant is factored accordingly. The problem of calculating the vibrational frequencies is thus divided into two parts: solution of a linear equation for the single frequency of species \( B_2 \) and of a quadratic equation for the pair of frequencies of species \( A_1 \).

On the other hand, it is often of interest to calculate force constants from observed vibrational frequencies. However, it is not generally possible to derive analytical expressions for the force constants as functions of the frequencies and the molecular geometry. The calculation is necessarily an iterative one. Starting with a set of assumed force constants – usually obtained by analogy with similar bonds in other molecules – the values are refined until a suitable set is found. The set that yields the best agreement between calculated and observed frequencies constitutes the accepted force field for the molecule.

From the above example, it is apparent that there may be (and usually are) more unknown force constants than observed frequencies. If no additional sources of data are available, it is necessary to make some assumptions to simplify the force field. Often some or all of the off-diagonal elements in the \( F \) matrix (Equation 23) are neglected, leading to the so-called VFF or modified valence force field (MVFF), respectively.

Assuming that a reasonable force field is known, the solution of the above equations to obtain the vibrational frequencies of water is not difficult. However, in more complicated molecules it very rapidly becomes a formidable one. If there are \( N \) atoms in the molecule, there are \( 3N \) total degrees of freedom and \( 3N - 6 \) for the vibrational frequencies. The molecular symmetry can often aid in simplifying the calculations, although in large molecules there may be no true symmetry. In some cases the notion of local symmetry can be introduced to simplify the calculation of vibrational frequencies and the corresponding forms of the normal modes of vibration.

Regardless of the force field chosen, the calculation of vibrational frequencies by the method outlined above is based on the harmonic approximation. Tabulated values of force constants can be used to calculate vibrational frequencies, for example, of molecules whose vibrational spectra have not been observed. However, as anharmonicities have been neglected in the above analysis, the resulting frequency values are often no better than \( \pm 5\% \) with respect to those observed.

For the example of the water molecule, it is of interest to calculate the forms of the vibrational modes, as obtained from the evaluation of the matrix \( L = UL \). The results can be presented most simply in the form shown in Figure 8. The calculation of the specific form of the normal modes is relatively complicated, although with the aid of current computer programs it becomes routine – at least for relatively simple molecules.

It is apparent from Figure 8 that the normal modes of vibration of the water molecule, as calculated from the eigenvectors, can be described approximately as a symmetrical stretching vibration \((v_1)\) and a symmetrical bending vibration \((v_2)\). It should be emphasized that the two normal modes of species \( A_1 \) are linear combinations of the two internal symmetry coordinates given by Equations (56) and (57). On the other hand, as there is only one symmetry coordinate of species \( B_2 \) in this

\[ v_1(A_1) \quad v_2(A_1) \quad v_3(B_2) \]

Figure 8 The normal modes of vibration of the water molecule.
case, it is identical with the normal coordinate shown for $v_3$ and can be correctly described as an antisymmetric stretching vibration.

It has been shown that the potential energy distribution provides an approximate method to evaluate the relative contribution of each symmetry coordinate to a given normal mode of vibration. From the definition of the symmetry coordinates (Equation 59), the relation (Equation 69)

$$ LFL = \Lambda $$

or (Equation 70)

$$ \sum_{pp'} L_{pp'} L_{p'k} F_{pp'} = \lambda_k \quad k = 1, 2, \ldots, 3N - 6 $$

(70)

can be derived. As the diagonal elements of $\mathbf{F}$ are usually at least an order of magnitude greater than the off-diagonal elements, the relation (Equation 71)

$$ \frac{1}{\lambda_k} \sum_p \sum_{pp'} L_{pp'}^2 F_{pp} \approx 1 \quad k = 1, 2, \ldots, 3N - 6 $$

(71)

is approximately equivalent to Equation (70). Each term on the left-hand side of Equation (71) represents the approximate contribution of each symmetry coordinate $S_p$ to the normal coordinate $Q_k$. The evaluation of this potential-energy distribution, and also the form of the normal vibrations, is usually carried out by current computer programs for the calculation of vibrational frequencies.

### 4.9 Characteristic Group Frequencies

Organic chemists are familiar with the use of infrared spectroscopy to identify functional groups in an unknown compound. This method of qualitative analysis is possible because the infrared absorption bands of many common functional groups vary but little from one molecule to another. For example, the band assigned to the carbonyl group, C=O, in ketones is usually found in the range 1710 – 1720 cm$^{-1}$. Similarly, in aldehydes it is between 1715 and 1735 cm$^{-1}$ and in organic acids from 1750 to 1770 cm$^{-1}$. The assignment of these bands to the carbonyl group implies that the normal modes of vibration corresponding to the observed frequencies are localized, that is, they involve only (or at least primarily) the internal coordinate that is the variation in the length of the C=O bond. Such assignments, which have been established empirically, are very useful, although they should be applied with caution. In this particular case the vibrational frequency associated with the carbonyl group is characteristic because the force constant of the carbon–oxygen double bond has approximately twice the value of the nearby single bonds. Substitution on an adjacent carbon atom will, however, produce frequency shifts, as indicated above.

From a theoretical point of view, if the matrices $\mathbf{G}$ and $\mathbf{F}$ are expressed in internal coordinates, the vibrational frequencies are determined from the eigenvalues of their product (Equation 31). In the case of a carbonyl compound, the change in the C=O distance could be chosen as the internal coordinate associated with the element $(\mathbf{GF})_{11}$. In the limit as either off-diagonal element $(\mathbf{GF})_{12}$ or $(\mathbf{GF})_{21}$ is much smaller than the diagonal element $(\mathbf{GF})_{11}$, the chosen internal coordinate becomes a normal coordinate, that is, it is “uncoupled” from the rest of the molecule. The normal coordinate is then localized and the observed frequency can be correctly described as a carbonyl vibration.

A more complicated example of characteristic group frequencies can be illustrated by consideration of the methyl group, CH$_3$, as shown in Figure 9. It is assumed in this model that the methyl group is attached to the molecular framework, represented here by an infinite mass. If the symmetry of the methyl group is not modified by the presence of the molecular framework, the point group is $3v$ and the analysis can be carried out as illustrated in section 4.8. The results are summarized in Table 6, where the figures given in the last line were calculated with the use of Equation (51). Application of the magic formula yields the reduced representation for the $3N = 15$ degrees of freedom of the methyl group attached to the mass X. Removal of the external coordinates leads to the result shown in the last column for the vibrational degrees of freedom, $3A_1 \oplus 3E$.

The 10 internal coordinates for the attached methyl group can be combined to form the symmetry coordinates

Table 6 The character table for the point group $3v$ and the analysis of the methyl group.

---

2023-07-21
given by Equation (72):

$$S_1 = \frac{1}{\sqrt{6}}(\Delta r_1 + \Delta r_2 + \Delta r_3)$$

species $A_1$:  

$$S_2 = \frac{1}{\sqrt{6}}(\Delta \alpha_{23} + \Delta \alpha_{31} + \Delta \alpha_{12} - \Delta \beta_1 - \Delta \beta_2 - \Delta \beta_3)$$

$$S_3 = \Delta R$$

and Equation (73):

$$S_{4a} = \frac{1}{\sqrt{6}}(2\Delta r_1 - \Delta r_2 - \Delta r_3)$$

$$S_{5a} = \frac{1}{\sqrt{6}}(2\Delta \alpha_{23} - \Delta \alpha_{31} - \Delta \alpha_{12})$$

$$S_{6a} = \frac{1}{\sqrt{6}}(2\Delta \beta_1 - \Delta \beta_2 - \Delta \beta_3)$$

$$S_{4b} = \frac{1}{\sqrt{6}}(\Delta r_2 - \Delta r_3)$$

$$S_{5b} = \frac{1}{\sqrt{6}}(\Delta \alpha_{31} - \Delta \alpha_{12})$$

$$S_{6b} = \frac{1}{\sqrt{6}}(\Delta \beta_2 - \Delta \beta_3)$$

$$E$$

It is then apparent that the three normal modes of vibration of species $A_1$ are linear combinations of the three symmetry coordinates given by Equation (72). The three frequencies corresponding to these three normal modes are by convention designated by $v_1$, $v_2$ and $v_3$. The symmetry coordinates of species $E$ given by Equation (73) consist of three pairs, identified by the subscripts $a$ and $b$. The coordinates labeled $a$ are symmetric with respect to the plane defined by $H_1$, $C$ and $X$, while the three labeled $b$ are antisymmetric. Appropriate linear combinations of the three members of each pair are the normal coordinates of this species. Either set of three symmetry coordinates, when substituted into the secular determinant, yields the corresponding vibrational wavenumbers of the modes $v_4$, $v_5$ and $v_6$. Representative results are summarized in Table 7.

The fourth column in Table 7 presents an evaluation of the contribution of each symmetry coordinate to a given normal mode of vibration of the methyl group. It is obvious that the often-used descriptions, as given in the last column of Table 7, are only approximate. It should be noted that the quantitative evaluation of the contribution of each symmetry coordinate to a given normal mode can be estimated by the calculation of the potential energy distribution (see Equation 71).

### 4.10 Spectroscopic Selection Rules

The relation between classical and quantum mechanics was pointed out in section 2.2. There it was shown that the difference between successive energy levels for the harmonic oscillator in quantum mechanics, when divided by Planck’s constant, yields the value of the vibrational frequency of the equivalent classical oscillator. This result is an example of the correspondence principle.

In the preceding section the vibration of polyatomic molecules is treated in a purely classical manner. With the use of normal modes the molecular vibrations become separated, each possessing a characteristic vibrational frequency. It then becomes possible to consider each normal mode as a quantum-mechanical oscillator, thanks to the correspondence principle. This fact is of extreme importance in vibrational spectroscopy, as it permits the calculation of the harmonic frequencies of vibration of the molecules with the use of the methods of classical mechanics (see section 3.5). The extension of the model to include the anharmonicity provides a basis for the qualitative interpretation of observed overtones and combinations of the fundamental vibrational frequencies.

In absorption spectroscopy the electric vector $\mathbf{E}$ of the incident radiation couples with the electric dipole moment $\mathbf{m}$ of the molecular system. The resulting time-dependent perturbation of the Hamiltonian (Equation 74),

$$H = -\mathbf{m} \cdot \mathbf{E}$$

(74)

induces a transition in the molecule and a corresponding absorption of energy. The probability per second of the transition from the state $n$ to the state $m$ is given by the Einstein coefficient for absorption, which can be written in the following form (Equation 75):

$$B_{n \rightarrow m} = \frac{8\pi^3}{3\hbar^2} \left( m|m_x|^2 + (m|y|^2 + (m|m_z|^2) \right)$$

(75)

This result is obtained by application of time-dependent perturbation theory.\(^6\) It also applies to the processes of spontaneous and induced emission. It should be noted that the factor before the brackets on the right-hand side of Equation (75) depends on the units employed and is important for the purposes of this article.

\(^a\) The wavenumber of these modes, and also the relative contributions of the different symmetry coordinates, are very sensitive to the value of the force constant for the CX bond.
In Equation (75) the notation of Dirac has been used to represent the appropriate integrals. Thus, for example (Equation 76),
\[
(m|m_X|n) = \psi^*_m m_X \psi^n \, dt
\]  
where \(\psi_n\) and \(\psi^m\) are the wave functions for the initial and final states, respectively, and \(dt\) represents the volume element in the space in question. For readers familiar with quantum mechanics it is apparent that when \(n = m\), Equation (76) expresses the average value of the \(x\)-component of the dipole moment of the molecule in that state. However, when \(n \neq m\) the integral in Equation (76) is known as the transition moment for this component. This, and the two analogous terms in Equation (75), determine the selection rules for this transition. Clearly, if all three transition moments are equal to zero, the transition cannot take place – it is said to be forbidden.

The vanishing (or nonvanishing) of an integral of this type can be established by consideration of the symmetry of the integrand. It is here again that group theory, as outlined in section 4.2, plays an important role.\(^{(5)}\)

In the rigid-rotator approximation, the energy was written as the sum given by Equation (11). To the same degree of approximation the wave function for a free molecule is simply the product in Equation (77):
\[
\psi \approx \psi(\text{rot})\psi(\text{vib})
\]  

The dipole moment in Equation (74) has been expressed in space-fixed coordinates \(X, Y, Z\) in the equations that follow. However, it is necessary to establish a Cartesian coordinate system \(x, y, z\) attached to the molecule and related to the space-fixed system by Equation (78):
\[
m(X, Y, Z) = \Phi m(x, y, z)
\]  
where \(\Phi\) is a three-by-three matrix whose elements are direction cosines connecting the various pairs of axes.\(^{(4)}\)

With the use of Equations (77) and (78) the transition moment for the component \(m_X\) becomes (Equation 79)
\[
\langle m|m_X|n \rangle = \psi^*_m(\text{rot}) \Phi_X \psi^*_n(\text{rot}) \, d\tau_{\text{rot}}
\]
\[
\times \psi^*_m(\text{vib}) m_X \psi^*_n(\text{vib}) \, d\tau_{\text{vib}}
\]
\[
+ \psi^*_m(\text{rot}) \Phi_X \psi^*_n(\text{rot}) \, d\tau_{\text{rot}}
\]
\[
\times \psi^*_m(\text{vib}) m_X \psi^*_n(\text{vib}) \, d\tau_{\text{vib}}
\]
\[
+ \psi^*_m(\text{rot}) \Phi_X \psi^*_n(\text{rot}) \, d\tau_{\text{rot}}
\]
\[
\times \psi^*_m(\text{vib}) m_X \psi^*_n(\text{vib}) \, d\tau_{\text{vib}}
\]  

To separate completely the integrals over rotational and vibrational coordinates, each component of the dipole moment is expanded about the equilibrium configuration in a Taylor’s series in normal coordinates. That is (Equation 80),
\[
m_X = m^0_X + \sum_{k=1}^{3N-6} \frac{\partial m_X}{\partial Q_k} Q_k + \cdots
\]  
and similarly for the other components. The higher terms in Equation (80), which account for the so-called electrical anharmonicity, are almost invariably neglected. Expressions of the form of Equation (80) for the various components are substituted into the three equations for the matrix elements, Equation (79) being one of them. Then, for example, the first term of Equation (79) becomes (Equation 81)
\[
\langle m|m_X|n \rangle = m^0_X \psi^*_m(\text{rot}) \Phi_X \psi^*_n(\text{rot}) \, d\tau_{\text{rot}}
\]
\[
+ \sum_{k=1}^{3N-6} \left( \frac{\partial m_X}{\partial Q_k} Q_k \psi^*_m(\text{vib}) \psi^*_n(\text{vib}) \right) \, d\tau_{\text{vib}}
\]
\[
\times \psi^*_m(\text{rot}) \Phi_X \psi^*_n(\text{rot}) \, d\tau_{\text{rot}}
\]  
where the integral over the vibrational coordinates normalizes to unity in the first term. Evaluation of integrals such as the first of Equation (81) results in the rotational selection rules that govern pure-rotational transitions in the microwave and far-infrared spectra of gases. These transitions involve no change in the vibrational state of the molecule.

The second term in Equation (81) contains the product of two integrals, one over rotational coordinates and the other over vibrational coordinates. Therefore, the nonvanishing of this term places simultaneous restrictions on changes of rotational and vibrational states. It is the origin of the selection rules for rotation–vibration absorption bands in the infrared spectral region. The evaluation of the integrals over rotational coordinates depends on the type of rotator involved, being relatively straightforward for linear or symmetric tops (see section 3.8).

The integrals over the vibrational coordinates in Equation (81) can be easily calculated in the harmonic approximation. In this case the properties of the Hermite polynomials yield directly the vibrational selection rule \(\Delta v_k = \pm 1\), where \(v_k\) is the vibrational quantum number for the \(k\)th normal mode. As most molecules are in their vibrational ground state \((v_k = 0\text{ for all values of } k)\) at ordinary temperatures, the most important features in the absorption spectrum of a molecule are those corresponding to the transitions \(v_k = 0 \Rightarrow v_k = 1\) for a given \(k\). This process is the absorption of but a single
quantum of vibrational energy. The absorption band observed in the infrared region is then referred to as a vibrational fundamental.

The selection rule given above, $\Delta \nu_k = \pm 1$, applies in the harmonic approximation; it will break down when anharmonicity is important. The effect of anharmonicity is (i) to modify the regular spacing of energy levels and (ii) to relax the harmonic selection rule. Thus, in the spectra of real molecules, absorption features are often observed at frequencies of approximately $2\nu_k$, $3\nu_k$, etc. the overtones, and at approximately $\ell\nu_k \pm \ell'\nu_k (\ell, \ell' = 1, 2, \ldots)$, the combinations. The quantitative analysis of these effects requires the addition of anharmonic terms in the potential energy. They have been neglected in treatments of all but the simplest (triatomic) polyatomic molecules.

### 4.11 Symmetry and Selection Rules

The vanishing (or nonvanishing) of an integral such as those given in Equation (79) can be determined by consideration of the symmetry properties of the integrand. It is sufficient to recall that in elementary calculus the symmetry (odd or even) of a function determines the value of its integral between symmetric limits. The same principle can be generalized and applied to the present problem. Thus, the symmetry properties of an integral such as Equation (82)

$$
\psi_m^+(\text{vib})m_0^0\psi_n(\text{vib}) \Delta r_{\text{vib}}
$$

(82)
can be established by consideration of the symmetry of each factor in the integrand. This approach to the problem is general, although in certain cases, particularly when degenerate wavefunctions are involved, it can be complicated. The interested reader is referred to the book by Wilson, Decius and Cross for the analysis of this problem. (3)

In its simplest form, as the IR of each factor in the integrand of Equation (82) can be established with reference to the symmetry group of the molecule, the overall symmetry of the integrand can be determined. If the IR for each factor has been found, their direct product describes the resulting symmetry. This representation, which can then be reduced, viz. (Equation 83)

$$
\Gamma^{(\nu_1)} \otimes \Gamma^{(\nu_2)} \otimes \Gamma^{(\nu_3)} = \sum \mu_H T_E
$$

(83)
is used to determine the selection rule for any transition $n \Rightarrow m$. In Equation (83), $\Gamma^{(\nu_1)}$ and $\Gamma^{(\nu_2)}$ are the IRs of the initial and final states, respectively, while in this example the $x$-component of the dipole moment belongs to the IR $\Gamma^{(\nu_1)}$. The general rule follows. If the reduced representation, as given by the right-hand side of Equation (83) does not contain the totally symmetric IR, $\Gamma^{(1)}$, the integral given by Equation (82), is equal to zero. The transition $n \Rightarrow m$ involving the $x$-component of the dipole moment is then forbidden. It should be noted that the initial state $n$ is not necessarily the ground state of the molecule.

As an illustration of the analysis outlined in the preceding paragraph, consider a fundamental absorption band of the ethane molecule. The symmetry of this molecule, which was described in section 4.7, leads to the character table given as Table 4. The structure of the reduced representation is then established with the use of the magic formula. These results are shown in the last two columns of Table 4. For fundamental transitions, those which originate from the (always) totally symmetric ground state of the molecule, their symmetry is thus described by $\Gamma^{(g)} = \Gamma^{(1)}$. From Table 4 it is apparent that there are two normal modes of symmetry $A_{2u}$. The symmetry of the dipole moment of the molecule is characterized by the components $T_x, T_y$, of symmetry $A_{2u}$, and the pair of components $(T_x, T_y)$, of symmetry $E_u$.

If, for example, a fundamental transition such as $A_{1g} \Rightarrow A_{2u}$ is considered, Equation (81) becomes Equation (84):

$$
A_{1g} \otimes A_{2u} \otimes A_{2u} = A_{1g}
$$

(84)
as can be easily established by multiplying the characters given in Table 4. Here it has been assumed that it is the $z$-component of the dipole moment that plays an active role in the transition. For this example, then, these fundamental transitions are allowed, as the right-hand side of Equation (84) contains the totally symmetric IR, $A_{1g}$.

For the three vibrational fundamentals of species $E_u$, only the $x, y$ coordinates of the dipole moment can provide infrared activity. This result is apparent from Equation (85):

$$
A_{1g} \otimes E_u \otimes E_u = A_{1g} \otimes A_{2g} \otimes E_g
$$

(85)
which is established by taking the appropriate products of the characters given in Table 4 and making the reduction of the representation with the use of the magic formula. As Equation (85) contains the totally symmetric representation $A_{1g}$, these vibrational fundamentals of ethane are active in its infrared spectrum. The other normal modes of this molecule, as summarized in the right-hand column of Table 4, cannot be infrared active.

The symmetry arguments presented in the preceding two paragraphs are general. They apply not only to the vibrational fundamentals, but also to the overtones and combinations. However, for the vibrational fundamentals they lead to a very simple rule, namely that for a normal mode to produce a fundamental transition it must belong to an IR which also contains a component of the
dipole moment. The more general method of analysis, as described above, is presented in more detail in a number of advanced texts.\(^{(3,6,8)}\)

### 4.12 Absorption Intensities

From the above discussion, it is apparent that the possibility of absorption of radiation by a molecule depends on its dipole moment in the case of pure-rotational spectra and on its dipole moment derivatives for vibrational spectra. Hence it is not surprising that the observed intensities of absorption lines or bands can be used as quantitative measures of the molecular dipole moment and its derivatives.

If a beam of light of intensity falls on a layer of sample material of infinitesimal thickness \(d\), the decrease in intensity of the beam is given by Lambert’s law (Equation 86):

\[
-\frac{d}{I_0} = \alpha d \ell
\]

where \(\alpha\) is the absorption coefficient. This expression can be integrated to yield

\[
\ln \frac{I}{I_0} = -\alpha \ell
\]

where \(\ell\) is the thickness of the sample and \(I_0\) is the intensity of the radiation incident on it. As the absorption coefficient, \(\alpha\), is proportional to \(N_iB_{nm}\), light absorption depends on the number of molecules present in the initial state of the system, in addition to the nonvanishing of the Einstein coefficient. The former condition is, of course, the origin of Beer’s law, the basis of the application of absorption spectroscopy in quantitative analysis. It is important to note that from a theoretical point of view, the absorption coefficient is proportional to the area of a given absorption band and not necessarily to its peak height. This question will be treated in Section 6 in connection with the analysis of band shapes.

### 5 SPECTRA OF GASES AND VAPORS

The rotational transitions which accompany a given vibrational transition in a polyatomic molecule produce a rotational structure on the infrared absorption band. For molecules with relatively large moments of inertia, this structure is often not observed, particularly at relatively low spectral resolution. However, small molecules in the gaseous phase yield spectra with easily resolved fine structure that can provide considerable information.\(^{(9)}\)

#### 5.1 Diatomic and Linear Molecules

The energy of a rotating, vibrating diatomic molecule was considered in Section 2.3. There it was shown that its energy is given by Equation (12), at least in the rigid-rotor approximation. This model was then generalized to take into account vibrational anharmonicity, rotation–vibration coupling and centrifugal distortion (Equation 13).

The fundamental rotation–vibration band of \(\text{HCl}\) is presented in Figure 10 as an example. The series of lines on the low-frequency side constitute the P branch, which arises from the selection rule \(\Delta J = -1\). The analogous features on the high-frequency side form the R branch \((\Delta J = +1)\). This spectrum was obtained under medium resolution. However, it is sufficient to show that each “line” in the rotational fine structure is in fact a doublet. This splitting of each line is due to the isotope effect. Specifically, the observed spectrum can be considered to be the superposition of two spectra, those of \(\text{H}^{35}\text{Cl}\) and \(\text{H}^{37}\text{Cl}\). Those rotational lines that are at lower frequencies are due to the isotopic species with the higher moment of inertia. The relative intensities of the two series of lines is a direct measure of the isotopic ratio for the chlorine atom in natural abundance. The gap in the middle of the spectrum is a manifestation of the selection rules, for which \(\Delta J = 0\) is forbidden.

Those polyatomic molecules for which, in the equilibrium configuration, all of the atoms lie along a straight line, can be analyzed similarly. In this case there are \(3N - 5\) normal modes of vibration, each with a wavenumber \(\tilde{\nu}_k\). The vibrational energy is given by Equation (88):

\[
\frac{E_{\text{vib}}}{\hbar c} = \sum_{k=1}^{3N-5} \tilde{\nu}_k \left( \nu_k + \frac{1}{2} \right)
\]

in the harmonic approximation, where \(\nu_k = 0, 1, \ldots, 3N - 5\). However, in the case of degeneracy, in which two modes have the same frequency, two identical terms in Equation (88) will be obtained. Thus, it is convenient to rewrite this equation in the following form (Equation 89):

\[
\frac{E_{\text{vib}}}{\hbar c} = \sum_i \tilde{\nu}_i \left( \nu_i + \frac{d_i}{2} \right)
\]
where the summation is now over all wavenumbers and the degree of degeneracy of each mode is equal to \( d_i \).

The addition of the rotational contribution to the energy, as given by the second term on the right-hand side of Equation (12), to Equation (89) leads to Equation (90):

\[
\frac{E_{\text{vib}} + E_{\text{rot}}}{\hbar c} = \sum_i \varepsilon_i \left( \nu_i + \frac{d_i}{2} + B_i \lambda \left( J + 1 \right) \right)
\]

(90)

in the rigid-rotor, harmonic oscillator approximation. Once again, this result can be generalized to include the effects of anharmonicity, centrifugal distortion and rotation–vibration coupling. It should be noted that consideration of the anharmonicity will introduce cross-terms between the various modes, which, strictly, are no longer normal modes of vibration. Furthermore, a relatively more important contribution to rotation–vibration coupling arises in this case from Coriolis forces for which a term must be added to take into account the angular momentum around the molecular axis. This term, which enters for modes involving bending of the molecule, requires the definition of an additional quantum number, \( \ell = 1, 2, \ldots \). In the case of bending modes the condition imposed on this quantum number, \( J = \ell, \ell + 1, \ell + 2 \ldots \), results in certain missing rotational lines and in splitting of others (ell doubling) due to the removal of the twofold degeneracy. While these effects are essential in the quantitative analysis of the rotation–vibration spectra of small molecules, they become less important as the moment of inertia increases (and hence the value of \( B_i \) decreases).

As a first approximation, the rotation–vibration spectrum of a linear molecule can be interpreted on the basis of Equation (90). However, the appropriate selection rules must be applied. In the case of a diatomic molecule the selection rule \( \Delta J = \pm 1 \) was used because the change in dipole moment is of course along the molecular axis. The same rule applies for linear polyatomic molecules when the dipole moment derivative is similarly directed. However, for vibrational fundamentals arising from bending vibrations of linear molecules, the dipole moment variation is oriented perpendicular to the molecular axis. The selection rule in this case is \( \Delta J = 0, \pm 1 \). Reference to Figure 2 then shows that the transitions of the type \( \Delta J = 0 \) will result in a series of lines at approximately the same wavenumber. These features constitute the \( Q \) branch in the rotation–vibration spectrum.

It is of interest to regard the infrared spectra of a simple linear molecule on the basis of the general theory presented above. As an example, consider the carbon dioxide molecule, whose equilibrium configuration is described by the point group \( \infty h \). The three fundamental vibrations of this molecule are represented in Figure 11. It should be noted that \( \nu_1 \) is doubly degenerate, leading to a nonzero angular momentum about the molecular axis and the symbol \( \Pi \) for the IR. Only the two vibrational fundamentals \( \nu_3 \) and \( \nu_2 \) are infrared-active.

The infrared spectrum of carbon dioxide in the region of its vibrational fundamental \( \nu_3 \) is shown in Figure 12. This band, which arises from the asymmetric stretching vibration, displays the characteristic P–R branches, analogous to those in the spectrum of a diatomic molecule. Furthermore, the intensity distribution of these branches is similar as illustrated in Figure 10 for hydrogen chloride. A weak, alternating variation in the intensities of the individual lines can be detected in Figure 12. This intensity pattern is due to the effect of the spins of the nuclei that are interchanged under the inversion operation.\(^{19}\)

The \( \nu_2 \) fundamental absorption band of carbon dioxide is presented in Figure 13. It is characterized by an intense Q branch, which arises from the series of lines due to the \( \Delta J = 0 \) transitions. These lines are not superimposed because the moments of inertia of the molecule are not exactly the same in the fundamental and first excited vibrational states. Under high resolution these lines can be clearly resolved in this case. The P and R branches
Figure 13 Portions of the infrared spectrum of carbon dioxide gas: the $v_2$ fundamental.

In Figure 13 also display the characteristic intensity distribution. The detailed analysis of a perpendicular band such as this one requires inclusion of the effect of Coriolis forces, as the angular momentum about the molecular axis is not equal to zero ($\ell = 1$).

From this brief summary of the infrared spectra of linear molecules, it is seen that the vibrations can be classified as stretching or bending modes. The former give rise to parallel bands, while the latter are characterized by perpendicular bands. These descriptions refer to the direction of the dipole moment variation with respect to the molecular axis. The most obvious difference between parallel and perpendicular bands is in the absence or presence, respectively, of the Q branch. Although for larger molecules in the gas phase the rotational structure of absorption bands may not be resolvable, the observed band envelopes often allow parallel and perpendicular bands to be distinguished.

5.2 Spherical Rotators

The term “spherical top” is employed to describe a molecule for which, in its equilibrium configuration, all three moments of inertia are equal (see section 3.8). Then, as for linear molecules, the energy in the rigid-rotator approximation is given by Equation (43). However, it should be noted that the degeneracy of the rotational levels becomes equal to $(2J + 1)^2$. This result has an effect on the intensity distribution of a given branch, or its envelope, of an absorption band.

Most molecules in this class whose rotation–vibration spectra have been studied have tetrahedral symmetry. Thus, from the character table for point group $d_4$

it is seen that infrared activity is limited to triply degenerate vibrations of species $F_2$. As the selection rules appropriate to the $F_2$ fundamentals are $\Delta J = 0, \pm 1$, rotation–vibration bands with a simple P–Q–R branch structure are predicted. However, as the vibrational levels are degenerate in this case, the effect of Coriolis interaction can become important. This contribution to rotation–vibration interaction results in splitting of the triply degenerate levels into three distinct energies.

The magnitude of the Coriolis splitting varies considerably from one band to another. This fact is exemplified in Figure 14, where the spectrum of the $v_4$ fundamental of methane is presented. Although the $v_3$ band exhibits the expected simple structure, the $v_4$ band is seriously perturbed as a result of interaction with the nearby infrared-inactive vibration $v_2$.

From the above example of the infrared spectrum of a spherical rotator, it should be obvious that a complete, quantitative analysis of the rotation–vibration spectrum is not straightforward. Although the broad features of a vibrational fundamental of a molecule in this class are similar to those of a linear molecule, Coriolis interaction often complicates the interpretation.

5.3 Symmetric Rotators

In Equation (45) for the rotational energy of a rigid symmetric top, (Equation 91)

$$\frac{E_{\text{rot}}}{\hbar c} = BJ(J + 1) + (C - B)K^2$$

where the rotational constants expressed in wavenumbers are defined with respect to the principal axes. Note that in this case the $c$-axis has been chosen as the axis of symmetry; thus, $\ell = B \neq C$. In Equation (91), the rotational quantum numbers are defined as before, namely, $J = 0, 1, 2, \ldots$ and $K = 0, \pm 1, \pm 2, \ldots, \pm J$. If the rotator is an oblate spheroid, $C < B$ and the second term in Equation (91) is negative. For the prolate top this
term is positive (if the \( a \)-axis is chosen to be the unique one, the axis of symmetry, \( B = C \) and the rotational constant \( C \) is replaced by \( A \) in Equation 91). As in this approximation the energy depends on \( K^2 \), each level for \( |K| > 0 \) is doubly degenerate. The sign, for a given value of \( K \), represents classically the direction of rotation of the angular momentum about the symmetry axis. Finally, it is apparent that if \( B = C \), Equation (91) reduces to the spherical-top expression.

As a first approximation the energy of a symmetric-top molecule can be written as the sum of those of a rigid rotor and \( 3N - 6 \) harmonic oscillators. However, in a higher approximation it is often necessary to take into consideration the effect of molecular vibrations on both moments of inertia. For nondegenerate vibrations it is usually sufficient to add terms that represent simple rotation–vibration coupling. For degenerate vibrations, however, the effect of Coriolis forces is much more important. As in the case of spherical rotators, they can produce a coupling of two vibrations of different species that increases with the rotational energy and a splitting of the degenerate vibrational levels. This effect is more important if the frequencies of the two vibrations are not widely separated. For practical purposes, the selection rules outlined in the following paragraph are not modified by these interactions.

For symmetrical rotators the selection rules for rotational transitions that accompany a vibrational one depend on the direction of the transition moment with respect to the top axis. Thus, as in the case of linear rotators, parallel and perpendicular bands have different characteristic structures. For parallel bands, the selection rules are given by Equation (92):

\[
\Delta K = 0, \quad \Delta J = 0, \pm 1
\]

with the condition that \( \Delta J = 0 \) transitions do not take place when \( K = 0 \). The corresponding selection rules that determine the structure of perpendicular bands are (Equation 93)

\[
\Delta K = \pm 1, \quad \Delta J = 0, \pm 1
\]

The possible transitions are summarized in Figure 15(a) and (b).

If the interaction of rotation and vibration is weak, as is often the case, the above analysis indicates that the parallel bands of a symmetric rotator should exhibit the characteristic P–Q–R branch structure. However, the corresponding perpendicular bands are usually much more complicated because of the Coriolis forces. Furthermore, all nonplanar molecules in this class have the possibility of inversion. The most important case is certainly that of the ammonia molecule. It has a pyramidal structure whose equilateral triangular base is determined by the equilibrium positions of the three hydrogen atoms. Its symmetry group is thus \( 3v \). This structure can be inverted in the sense that the three protons can pass to equivalent positions on the other side of the nitrogen atom. The relatively low barrier to this process (approximately 5.8 kcal mol\(^{-1}\)) results in splitting of the vibrational energy levels. The separation of the two components corresponds to a frequency of 23.87 GHz, or approximately 0.79 cm\(^{-1}\). Thus, an absorption line is
Figure 16 A portion of the $\nu_3$ fundamental of ammonia.

readily observable at this frequency in the microwave region. The effect of this inversion process results in a doubling of the rotation–vibration spectrum, as shown in Figure 16. The two Q branches are clearly shown, each with its associated P and R branches.

5.4 Asymmetric Rotators

Very little can be said here concerning the rotation–vibration spectra of asymmetric rotators, except that they are in general very complicated. As indicated earlier, no analytical expression can be derived for the rotational energies of molecules in this class. However, computer programs are now available that provide a means of fitting observed rotational fine structure, as observed on vibrational bands in the infrared region.

6 SPECTRA OF NEAT LIQUIDS AND SOLUTIONS

The observed vibrational frequencies of molecules in neat liquids or in solution are often employed as a means of identification. However, it is well known that the frequency of a given mode of vibration of a molecule in the liquid state depends on the nature of the surrounding molecules. The vibrational frequency shifts displayed by a molecule as it passes from the free state (as in ideal gas) to its role as a molecule in a liquid environment is due to intermolecular forces. It may undergo interactions with identical molecules in a neat liquid or it may become a solute in a liquid solvent. The interaction of this molecule with its neighbors, which depends on physical quantities such as the polarity of the nearby molecules and their polarizability, have been employed in simple models of intermolecular interactions. Probably the earliest treatment of these so-called solvent effects was due to Kirkwood and to Bauer and Magat.\(^6\) Their model, which has been modified by many authors, provides the initial basis for the interpretation of the effect of the environment on the vibrational spectra of molecules in the liquid state.

6.1 Solvent Effects

The above approach to the evaluation of the environmentally induced frequency shifts provided a semiempirical basis of the analysis of solvent effects. It was useful in the days when infrared instrumentation was relatively primitive and spectroscopists were content to measure frequencies of vibration, or perhaps the widths of absorption bands. Such quantities yielded extremely valuable analytical information concerning molecular interactions in liquids. However, with the refinement of instrumentation (in particular the development of Fourier transform techniques), as well as an important evolution of the theory of molecular dynamics in condensed phases, it has become of interest to measure and interpret the exact profile of an absorption band of a molecule in the liquid state. This approach to the analysis of the profiles of absorption bands of liquid samples will be developed briefly in section 6.3.

Some infrared spectra of acetonitrile in the liquid state are presented in Figure 17. The spectrum of the neat liquid exhibits a strong absorption band at 2253 cm\(^{-1}\), which is assigned to the C≡N stretching vibration. The weaker feature at 2293 cm\(^{-1}\) is probably the first overtone of a mode approximately described as a C–C bond stretching.

Spectra of the same molecule in several commonly used solvents are also shown in Figure 17. It is apparent that the position of the minimum transmission of the C≡N stretching fundamental is a function of the molecular environment. On the other hand, the C–C overtone is relatively insensitive to the intermolecular forces. A careful inspection of these spectra reveals certain changes in the profiles of the observed bands. Both the widths of the C≡N stretching bands and their transmission in the wings vary with the solvent used. Furthermore, slight band asymmetries can be detected when the abscissae are developed. In particular, the broadening of the C≡N stretching band of acetonitrile provides evidence of hydrogen-bond formation with the methanol solvent. This particular interaction will be discussed in section 6.4.

6.2 Absorption Bandshapes

The shape of the wings of an absorption band of a small molecule in solution is primarily due to its hindered rotational (or orientation) motion. The effect becomes more clearly evident in the case of a diatomic solute molecule. Some early spectra of HCl in various solutions are shown in Figure 18, where they are compared with a schematic representation of the spectrum of the gas. The spectra of the dissolved molecule are characterized by the appearance of a central absorption peak analogous to the (forbidden) Q branch in the spectrum of the gas at \( v_0 \) and its shift to lower frequencies with increasing solvent perturbation. Furthermore, the wings of the bands become less prominent as the central feature increases in intensity. It should be noted that CCl₄, a commonly used solvent in organic analytical spectroscopy, is not as “inert” as is often supposed. Thus, the vibrational frequencies of a molecule (especially those involving H atoms) in this solvent do not correspond to those of the isolated molecule. Furthermore, the frequency shifts become greater in polar solvents, as exemplified by the spectrum of HCl in CH₂Cl₂.

6.3 Band Broadening

When a hypothetical isolated molecule interacts with electromagnetic radiation, the processes of absorption, induced emission and/or light scattering may result. The spectra obtained are characterized by the bands due to transitions between the various quantum states of the molecules. The fact that a given transition produces a broadened feature is fundamentally due to the uncertainty principle and the Doppler effect. These origins of spectral broadening are only important in the study of gaseous samples under extreme conditions (e.g. very low pressures and temperatures – as in the stratosphere). For the routine applications considered here, where a sample consists of a very large number of molecules in a liquid, the broadening and frequency shift of a given band is produced by the intermolecular interactions. Furthermore, the time dependence of these interactions results in characteristic band shapes or “profiles”.

In general, the shape of a spectral band can be described by a series of moments defined by Equation (94):

\[
M(n) \equiv \int_{-\infty}^{+\infty} (w - w_0)^n \rho (w) \, dw
\]

where \( n = 0, 1, 2 \ldots \) and \( w = 2\pi v \). The quantity \( w_0 \), which is known as the “shifted band origin”, corresponds to the peak position of a symmetric band. Clearly, when \( n = 0 \), the moment \( M(0) \) is just the area of the band, the absolute intensity referred to in section 4.12. The first
A characteristic feature of the hydrogen bond, as observed in its infrared spectrum, is the extreme broadening of the $\tilde{v}_b$ band. This behavior, which is unique to hydrogen-bonded systems, has been the subject of much discussion. Regardless of its origin, it is of obvious diagnostic value, as it is the most important criterion for hydrogen-bond formation.

An early infrared spectroscopic investigation of hydrogen bonding in methanol illustrates the specific information that can be obtained (Figure 19). From the results of this work it was possible to distinguish the absorption band associated with the O–H stretching vibration of the monomer in a relatively inert solvent from those resulting from dimers and higher polymers. The spectra were obtained from solutions of methanol in toluene. Spectrum A exhibits a relatively sharp band at 3607 cm$^{-1}$ which is assigned to the O–H stretching vibration of the monomer. This feature is clearly dominant in dilute solution. The broad band at 3502 cm$^{-1}$ arises from the formation of dimers as a result of hydrogen-bond formation. It can be considered to be characteristic of this type of interaction. The subtraction of the spectrum of the more dilute solution effectively eliminates the monomer band and reveals the weaker band at 3582 cm$^{-1}$. This band can thus be attributed to the stretching of a “free” OH group in the dimer. This result leads to the conclusion that the dimer has an open structure, rather than a cyclic one.

The example chosen here to illustrate the spectroscopic consequences of hydrogen-bond formation is from studies of the liquid state. It is of particular interest in demonstrating the evolution of this fundamental aspect of infrared
spectroscopy. More recent applications to crystals, glasses and, in particular, molecules of biological interest are described elsewhere in this volume.

7 SPECTRA OF SOLIDS

7.1 The Linear Diatomic Chain

The interpretation of the vibrations of crystalline solids is based on the one-dimensional model developed by Born.\(^6,\)\(^12\) This simple system was originally employed to estimate the specific heats of crystals, in particular, those of the sodium chloride structure. It has subsequently served as the basis for the interpretation of the vibrational spectra of crystals. The analysis of this model, the diatomic chain, will now be briefly summarized.

Consider a linear chain consisting of two types of atom arranged alternately, as shown in Figure 20. As indicated above, this one-dimensional model can be used to represent a simple ionic crystal. The distance \(d\) is then the dimension of the unit cell which contains two particles. The forces on atoms of type 1 and 2 are given by, respectively, Equation (95):

\[
F_{2n} = -f'(\rho_{2n} - \rho_{2n-1}) + f(\rho_{2n+1} - \rho_{2n}) = m_1 \ddot{\rho}_{2n}
\]  

(95)

and Equation (96):

\[
F_{2n+1} = -f'(\rho_{2n+1} - \rho_{2n}) + f'(\rho_{2n+2} - \rho_{2n+1}) = m_2 \ddot{\rho}_{2n+1}
\]  

(96)

where \(\rho_n\) is the displacement of atom \(n\) along the direction of the chain. The force constants \(f\) and \(f'\) are assumed to be different, at least in this initial formulation of the problem.

Periodic solutions of Equations (95) and (96) can be proposed in the form of Equation (97):

\[
\rho_{2n} = A_1 e^{2\pi i (n - nd)}
\]  

(97)

and Equation (98):

\[
\rho_{2n+1} = A_2 e^{2\pi i \frac{n}{2} k d}
\]  

(98)

Substitution of these expressions in Equations (95) and (96) leads to the pair of linear, homogeneous equations (99) and (100) for the amplitudes \(A_1\) and \(A_2\):

\[
[4\pi^2 \nu^2 m_1 - (f + f')]A_1 + (f e^{-\pi kd} + f' e^{\pi kd})A_2 = 0
\]  

(99)

and

\[
(f' e^{\pi kd} + f e^{-\pi kd})A_1 + [4\pi^2 \nu^2 m_2 - (f' + f)]A_2 = 0
\]  

(100)

A nontrivial solution of these equations exists only if the determinant of the coefficients vanishes. Thus, the secular determinant becomes Equation (101):

\[
f + f' - 4\pi^2 \nu^2 m_1 - (f e^{\pi kd} + f' e^{-\pi kd})
\]

\[
-(f' e^{\pi kd} + f e^{-\pi kd})
\]

\[
f' + f - 4\pi^2 \nu^2 m_2 = 0
\]  

(101)

whose roots are given by Equation (102):

\[
\nu^2 = \frac{f + f'}{8\pi^2} \left(\frac{1}{m_1} + \frac{1}{m_2}\right)
\]

\[
\pm \frac{1}{4\pi^2} \left[\left(\frac{f + f'}{2}\right)^2 \left(\frac{1}{m_1} + \frac{1}{m_2}\right)^2 - 4\nu^4 \sin^2(\pi kd)\right],
\]  

(102)

For the special case in which all bonds are identical, \(f = f'\), which implies equal spacing of the atoms, and Equation (102) reduces to Equation (103):

\[
\nu^2 = \frac{f}{4\pi^2} \left(\frac{1}{m_1} + \frac{1}{m_2}\right)
\]

\[
\pm \frac{1}{4\pi^2} \left(\frac{1}{m_1} + \frac{1}{m_2}\right)^2 - 4\sin^2(\pi kd\right) m_1 m_2
\]  

(103)

The vibrational frequencies calculated from Equation (103) are plotted as functions of the wavenumber \(k\) in Figure 21, where it has been assumed that \(m_1 < m_2\). Clearly, it is the positive roots of Equation (103) that are of physical significance. The curve that passes to the origin is called the acoustical branch, because the frequencies fall in the region of sonic or ultrasonic waves. The upper curve, referred to as the optical branch, represents frequencies in the optical (infrared) spectral region. The latter are of prime importance for the subject of this article.

The forms of the normal vibrations for each branch are given schematically in Figure 21 for the limiting values \(k = 0\) and \(k = 1/2d\). It should be noted that at \(k = 0\) the optical branch represents a simple stretching of the bond between the two atoms for which their center of mass remains fixed. As the two atoms are assumed to be different, the oscillating dipole moment which results can interact with incident radiation, producing absorption in the infrared region. The acoustic vibration, on the other hand, does not result in a change in dipole moment at \(k = 0\).
fixed in its unit cell. The second solution arises from translational motion of the rigid diatomic molecules. The approximate solutions given by Equations (104) and (105) are appropriate to the limiting case, $f \gg f'$. In general, $v_{\text{int}}$ exhibits some dependence on $k$. Nevertheless, the above approximation is the basis of the separation which is often made of internal and external motion in crystals containing molecules or polyatomic ions.

From the preceding analysis it should be apparent that the vibrational frequencies of this one-dimensional system spread over two distinct regions. For the acoustic branch the frequencies lie between zero and $(1/2\pi)\sqrt{2f/m_1}$, whereas for the optical branch they are between $(1/2\pi)\sqrt{f/\mu}$ and $(1/2\pi)\sqrt{2f/m_1}$. In each case the former values correspond to the origin of the wavenumber scale, $k = 0$, and the latter are the vibrational frequencies at the limit of the first Brillouin zone. This limit is equal to $k = 1/2d$ in this, the one-dimensional case. The distribution of frequencies within the two limits specified above is usually referred to as the density of vibrational states. Not all of these frequencies can result in spectroscopic features, as the question of selection rules must be considered.

### 7.2 Three Dimensions: Crystalline Solids

The static structure of a perfect crystal can be described by successive translations of a unit cell in space. This repetition constitutes a symmetry operation in the sense that all such unit cells are considered to be identical. Thus, a symmetry group of these operations can be defined. The application of this principle leads to the definition of the 230 space groups of crystallography. The justification for this model supposes that the crystal is infinitely large in three-dimensional space, or at least large with respect to the dimensions of the unit cell. A mathematical artifice, the so-called cyclic boundary conditions, is sometimes introduced to achieve the equivalent result.

In the application of interest in this article, it is the primitive unit cell that is employed to generate the three-dimensional space of the crystal. This cell, which is the smallest geometrical motif that can be defined, is in some cases identical with the crystallographic unit cell, although it may otherwise have half or one-quarter its volume. This question, which has been addressed in several references, is basic in the spectroscopic applications of crystallography, as the vibrational spectroscopy of crystals involves their dynamic, rather than their static, description. A starting point in the analysis of their dynamics is provided by the model of the diatomic chain, as outlined above.

The complexity of the three-dimensional vibrational problem increases very rapidly with the number of atoms in the unit cell. However, by analogy with the
one-dimensional model, solutions to the equations of motion can be written in the harmonic approximation as Equation (106):

\[
\rho_n = A_n \exp[2\pi i(vt - kx_n)]
\]

where \(\rho_n\) is a vector that specifies the displacement of atom \(n\) at a given instant. The amplitude and frequency of the descriptive wave in the crystal are represented by \(A_n\) and \(v\), respectively. The equilibrium position of each atom is located with respect to a suitable space-fixed origin by the vector \(x_n\), while \(k\) is the wave vector, a quantity that has the magnitude of reciprocal wavelength and is in the direction of propagation of the descriptive wave. As in the one-dimensional case, the dispersion relations determine the density of vibrational states in the crystal.

There are three dispersion curves for each particle in the primitive unit cell, as each has three degrees of freedom. Thus, for the simple example of a molecular crystal whose unit cell contains \(\sigma\) molecules, each of which is composed of \(N\) atoms, as many as \(3N\sigma\) separate curves (branches) may exist. Of course, the actual number of branches may be reduced owing to degeneracies in the system. Three of these degrees of freedom correspond to acoustic modes; hence there are up to \(3N\sigma - 3\) optical branches. The general form of the dispersion relations for such a system is sketched in Figure 22 for a given direction of the wave vector. The various branches have, in general, different shapes depending on the direction of \(k\).

As pointed out in the previous section in connection with the vibration of the diatomic chain, intramolecular forces are relatively strong in a molecular crystal. Hence the frequencies of the \(3N - 6\) vibrational fundamentals of a molecule in the gas phase are not severely modified when the molecule is in a crystalline environment. If there are \(\sigma\) molecules per unit cell, there are \(\sigma(3N - 6)\) possible “internal” frequencies although, degeneracies are usually present to reduce this number. As in the corresponding limiting case of the diatomic chain, these internal frequencies are usually only slightly dependent on the wave vector, \(k\).

The remaining degrees of freedom are derived from the \(3\sigma\) translational and \(3\sigma\) rotational motions of the (nonlinear) molecules. However, three of these degrees of freedom are responsible for the acoustic modes of the crystal, leaving \(6\sigma - 3\) as the maximum number of optical external modes. These latter, which are referred to by spectroscopists as the “lattice vibrations”, usually fall in the far-infrared region of the spectrum of a crystal.

### 7.3 The Factor-group Analysis of Crystals

The analysis of the infrared and Raman spectra of crystals is based on the notion of the factor group. In effect, if a perfect crystal can be described by a space group, a symmetry group that characterizes the unit cell can also be defined. Although it is not, strictly, a point group, it has the same form as a point group, viz. it is isomorphic. As only symmetry axes of order 1, 2, 3, 4 or 6 are possible for a unit cell that can fill three-dimensional space, only 32 such groups exist. They identify the crystal classes. On the basis of this argument, the space group of a given crystal can be factored in the following form (Equation 107):

\[
\Gamma = \otimes
\]

where \(\otimes\) represents here the (semi)direct product. It can be shown that the point group that is isomorphic with the unit cell group can be used to determine the normal modes of vibration of the molecules in the unit cell and the selection rules for the vibrational fundamentals. Once the appropriate unit-cell group has been identified, the vibrational analysis is similar to that of an isolated molecule.

As an illustration of the factor-group method, consider crystalline methyl chloride. The symmetry of the molecule is described by the point group \(\text{C}_{3v}\), and the discussion presented in section 4.9 is appropriate. With the use of the character table (Table 6) the vibrational analysis of the molecule can be made as before. The results are summarized in the first column of Figure 23. The internal vibrations are numbered in decreasing order of frequency, starting with the most symmetrical IR \(A_1\) in this case) following Herzberg. The three doubly degenerate frequencies of \(E\) species are numbered similarly. The representations of the six external degrees of freedom are also identified in Figure 23.

From the results of X-ray analysis, it is found that methyl chloride crystallizes in the side-centered orthorhombic system. Its space group is \(\text{C}_{2h}^{3}\) \(\equiv\) \(\text{Bm2}_1\) \(b\), with four molecules in the crystallographic unit cell. However, the primitive-symmetric or Wigner–Seitz cell contains only two molecules. They are located at sites
A species possible. In the present example, the three frequencies to be observed as doublets in the infrared spectrum field. These three internal vibrations will then be expected vibrations are not modified by the site symmetry in the summarized as follows. The three nondegenerate internal vibrations of the methyl chloride example can be on the right of Figure 23 is established by inspection of the space group. In this case the site group is also a subgroup of the symmetry group of the molecule. Thus, the correlation shown on the left of Figure 23 is easily established.

The required unit-cell group is as found by simply suppressing the superscript in the Schönflies notation for the space group. In this case the site group is also a subgroup of the unit-cell group. The correlation shown on the right of Figure 23 is established by inspection of the character tables (see Table 5).

The interpretation of the results obtained above by the analysis of the methyl chloride example can be summarized as follows. The three nondegenerate internal vibrations are not modified by the site symmetry in the crystal. The three degenerate modes of species are, however, split by the symmetry of the local crystalline field. These three internal vibrations will then be expected to be observed as doublets in the infrared spectrum because of this site splitting.

As there are two molecules per primitive unit cell, coupling of the molecular modes of vibration becomes possible. In the present example, the three frequencies of species in the molecule are split by this correlation (or dynamic) coupling. According to the character table for the group as found by simply suppressing the superscript in the Schönflies notation for the site group, both components of each doublet will be infrared-active. As for the three vibrations of species in the molecule, each has been subjected to site splitting. Furthermore, each component will be further split due to coupling with its partner in the unit cell. However, as shown in Figure 23, the doublets produced by the splitting of the species of the molecule in its site will produce one component in the infrared-inactive species. The other component passes to species and is therefore active. The overall result for the species of the molecule is to produce an infrared-active triplet for each of the frequencies, and.

The magnitudes of the static and dynamic splittings described above are in general of the same order of magnitude, viz. a few wavenumbers. They cannot, therefore, be distinguished unless systematic investigations of oriented single crystals can be made. Such studies of infrared dichroism with the use of polarized infrared radiation are of extreme value, not only for structural investigations of single crystals, but also in the determination of the optical properties of films. Examples include the problem of molecular orientation of films deposited on solid substrates and that of stretched polymers.

### 7.4 Polymers

The linear-chain model developed in section 7.1 served as the basis for the dynamic description of a crystal. It can also be employed in the analysis of the vibrations of polymers. It is often the case that the forces between successive motifs in a polymer chain are much stronger than the forces between adjacent chains. A given chain can then be developed by successive translation of the particular motif of which it is composed. The group of translational operations constitute the line group, while the particular motif represents an effective unit cell in this model.

Consider polyethylene as a polymer chain that can be analyzed by application of the line-group method. The repetitive motif is represented in Figure 24. The carbon skeleton of the extended chain is assumed to have a planar zigzag structure along the -direction and a plane of symmetry perpendicular to it. There is a binary axis of symmetry perpendicular to the plane of the carbon chain, passing through the center of inversion (i) shown in Figure 24, as well as another that passes through each carbon atom. The other symmetry elements are a screw axis and a glide plane, analogous to those encountered in crystallography. They are denoted here by and , respectively. The ensemble of operations associated with these elements, with the addition of the identity, form the factor group. It is isomorphic with the point group . The 18 degrees of freedom of the six-atom repeat unit can be classified as shown in Table 8 with the use of the method outlined in section 7.3.

As the polymer chain has been assumed to be isolated, the external motions of translation in the - and -directions, as well as the rotation about the -axis have

zero frequencies and can be removed, as for a gaseous molecule. These degrees of freedom are sometimes referred to as “nongenuine” vibrations. Translation in the $z$-direction is analogous to the acoustic vibrations of a crystal lattice, as described in the previous section. Thus, for in-phase motions of all repeat units this frequency is also equal to zero.

The number of vibrational modes in each IR is given in the last column of Table 8. Infrared activity is limited to the three species $B_{1u}$, $B_{2u}$ and $B_{3u}$. The two $B_{1u}$ modes are combinations of the symmetric stretching ($v_s$) and bending ($\delta$) coordinates illustrated in Figure 25. The $B_{2u}$ modes are combinations of the antisymmetric stretching mode ($v_a$) and the rocking coordinate ($\rho$), while the wagging coordinate ($\omega$) shown for species $B_{3u}$ can be identified with the corresponding normal coordinate.

The analysis presented above for the vibrations of extended, normal polymer chains can be generalized to include, for example, helical chains. This problem has been described in a number of references.$^{(6,12)}$ Furthermore, the question of the interaction of polymer chains in a solid has also been treated. It should be emphasized that in the development of these models it has been assumed that the chains are of infinite length, or at least that their symmetry under translation is preserved. In the case of chains of finite length, the problem becomes much more complicated, as the appropriate boundary conditions must be imposed at each end of the chain. The reader is referred to more advanced presentations for the effects of these conditions on the vibrational spectra of polymer chains.$^{(6,12)}$

### 7.5 Disordered Solids

A complete theoretical analysis of disordered solids has not as yet been developed. However, a qualitative description of these systems can be obtained on the basis of the preceding analysis of the vibrations of crystals. In section 7.3 the perfect crystal was taken as a model. However, if its translational symmetry is perturbed, the factor-group method can no longer be applied. Thus, the concept of a repetitive unit cell in space is no longer valid, as a given motif is not exactly reproduced by simple translations. Furthermore, the force field involved is not repetitive. Thus, there are three perturbations to spectroscopic analysis that are produced by the disorder of the system. The first of them has an immediate effect on the selection rules that govern vibrational transitions. All of the frequencies that contribute to the density of vibrational states in a given crystal become spectroscopically active. The result is a broadening of the infrared absorption bands, as can be seen from the simple example shown in Figure 26. The structural changes involved in the transitions from the pure crystal to a disordered system result in the other two effects, namely, modifications of the force field and kinetic effects that contribute to the effective $G$ matrix. Obviously, the quantitative treatment of this problem is difficult.
8 CONCLUSION

From the contents of this article, it is apparent that the basic theory of infrared spectroscopy was developed many years ago. The more recent evolution of this subject has been primarily in the areas of computational methods and instrumentation. The impact of computer science has made possible the numerical treatment of spectroscopic data and, in particular, the application of the Fourier transform technique. The future will certainly see advances in the development of rapid time-resolved infrared spectroscopy, which should soon become an invaluable tool in the study of chemical reactions.

On the purely theoretical side, there remains the fundamental problem of disordered systems. These include glasses and other amorphous materials, in addition to the liquid state. The latter can be considered to be a system that is disordered in both space and time. Although it is the state of matter most generally employed in analytical spectroscopy, it still presents the most difficult challenge to molecular theorists.

The vibrational spectroscopies are those producing the entire (or part) vibrational spectrum of a sample, i.e. the collection of transition energies between its vibrational states. The simplest way to cause vibrational excitation is to allow the chemical species in its vibrational ground state to absorb an energy quantum from electromagnetic radiation of an appropriate energy, i.e. in the medium infrared (IR) or in the far infrared (FIR) regions. Transmission–absorption IR spectroscopy comprises the analysis of the quanta that are actually absorbed by a polyatomic chemical species and those that are not absorbed (so are transmitted). Other IR techniques relate to the analysis of the radiation that is emitted, diffused, or reflected by the sample. Another way to obtain part or all of the vibrational spectrum of a chemical species is to look at the inelastic scattering of beams other than IR radiation. Raman spectrometry is the analysis of the ultraviolet (UV), visible or near infrared (NIR) radiation that is scattered inelastically by the sample. Inelastic neutron scattering (INS) is the analysis of the energy of formerly monochromatic neutron beams after inelastic scattering by the sample. Analyses of the number and energies of the vibrational transitions of the sample, detected by each technique, yield information on the geometric (molecular and crystallographic) structure of the sample and on the strength and nature of the chemical bonds it contains.

1 INTRODUCTION

Any chemical species containing more than one atom – polyatomic molecules, molecular ions, molecular radicals, and any crystal – can be described in terms of atomic positions, bond lengths, and bond angles. However, any atom vibrates around its equilibrium position, giving rise to vibrational modes. At absolute zero temperature all polyatomic chemical species lie at the vibrational ground state. However, they can undergo vibrational excitation, thereby occupying higher-energy vibrational states. The energy differences between nearest vibrational states lie in the medium and FIR ranges, generally defined by the wavenumber limits: 4000–400 cm⁻¹, i.e. 0.496 > E > 0.0496 eV for medium IR; and 400–10 cm⁻¹, i.e. 0.0496 > E > 1.24 × 10⁻³ eV for FIR.

The simplest way to cause vibrational excitation is to allow the chemical species to absorb an energy quantum from electromagnetic radiation of an appropriate energy, so giving rise to a vibrational transition from the ground state to an excited vibrational state. Analysis of the quanta that are actually absorbed by a polyatomic chemical species, and those that are not absorbed (so are transmitted), gives information on the vibrational structure of these species and, consequently, on its chemical and geometric structure. These are the fundamentals of transmission/absorption IR spectroscopy, which has been under continuous development since the late 19th century and has become one of the most widely used techniques for chemical analysis.¹

Over time, it has been recognized that other IR techniques (reflection, emission, and photothermal techniques) can also be applied, and that IR spectroscopy only gives partial information on the vibrational structure.
of any polyatomic species. In fact, selection rules apply to IR light absorption phenomena, so that only those vibrational modes associated with changes in the molecular dipolar moment can be directly excited.

Another way to observe the vibrational spectrum of a chemical species is to look at the inelastic scattering of beams other than IR radiation. When such beams are scattered by a polyatomic species, some photons lose or gain energy as a result of interaction with the vibrational states of the molecule. The vibrational spectrum is obtained by measuring the difference between the energies of the incident beam and the small fraction that is inelastically scattered. If the incident photons are of relatively high energy – UV, visible, or NIR – we are dealing with Raman spectroscopy. Raman observed that if a monochromatic high-energy radiation interacts with a chemical species, the scattered radiation is no longer monochromatic, Now containing photons whose energy is produced by the sum or the difference of the original radiation energy with the energies of some vibrational transitions of the chemical species. As the selection rules for Raman-active modes do not correspond to IR-active modes in centrosymmetric chemical species, and only partly correspond (generally) for noncentrosymmetric species, Raman spectroscopy is in most cases complementary to IR spectroscopy.

The vibrational spectra of polyatomic chemical species also can be probed by the inelastic scattering of particles other than photons. The use of electrons gives rise to the techniques of electron energy loss spectroscopy (EELS) and inelastic electron tunneling spectroscopy (IETS). The incident particles can be neutrons, giving rise to INS spectroscopy, or atoms, giving rise to atom scattering spectroscopy (ASS). These techniques, developed in the 1960s by physicists, have found application in surface chemistry and physics. However, some may also be applied to bulk solids, such as geological and inorganic materials.

2 VIBRATIONAL MODES OF INORGANIC SOLIDS

2.1 Molecular Species

The total number of degrees of freedom associated with a chemical species containing \( N \) atoms is \( 3N \). If this chemical species is a molecule in the gaseous state, three of these degrees of freedom are associated with its translations and another three to its rotations, so that in the most general case six modes are associated with external motion (rotations and translations). The remaining \( 3N - 6 \) degrees of freedom are associated with internal, i.e. vibrational, modes. However, if the molecule is linear, only two degrees of freedom are associated with rotation, because no rotational freedom exists around the molecular axis. Thus, in this particular case, the number of degrees of freedom associated with vibrations is \( 3N - 5 \). A complete treatment of the principles of vibrational spectroscopy is beyond the aim of this article. The methods for determination of the number and the optical activity of the vibrational modes of molecular species have been given elsewhere.\(^{3-8}\)

The \( 3N - 6 \) (or \( 3N - 5 \)) degrees of vibrational freedom give rise to vibrational modes that differ in their symmetry with respect to the symmetry elements of the molecular point group and in their multiplicity. The nondegenerate modes are denoted as A or B in relation to their symmetry or antisymmetry with respect to the rotation about the principal symmetry axis. Doubly degenerate modes and triply degenerate modes are denoted E and F, respectively. The subscripts g and u denote modes that are symmetric or antisymmetric, respectively, with respect to the center of symmetry (if any); the superscript symbols ' and " distinguish modes that are symmetric or antisymmetric, respectively, with respect to symmetry planes not containing the principal axis (\( \alpha \neq \alpha_i \)). The subscripts 1, 2, 3 are related to the symmetry with respect to other symmetry axes.

Character tables, which can be found in several vibrational spectroscopy books, allow the determination, for any molecular point group, of the species (or irreducible representations) in relation to the symmetry elements typical of that group. As discussed below, the classification in terms of a particular symmetry species determines the activity – IR activity, Raman activity, both IR and Raman activity, or inactivity – of any mode.

2.2 Crystalline Solids

When a crystalline solid is considered, the \( N \) atoms present in the smallest (primitive) Bravais cell must be taken into consideration to count the fundamental vibrational modes. They give rise to \( 3N \) total degrees of freedom, three of which give rise to translational modes of the cell as a whole, which are the acoustic modes. Thus, the vibrational degrees of freedom (optical modes) are, in this case, \( 3N - 3 \).

If the solid is molecular, the molecules (supposed to be formed by \( M \) atoms, where \( M = N/r \) with \( r \) being the number of molecules in the smallest Bravais cell) can be treated as for the gas phase, thus giving rise to \( 3M - 6 \) (or \( 3M - 5 \) if linear) vibrations for each molecule. The degrees of freedom associated with the external modes of every molecular unit (which are \( 6r \) for nonlinear molecules and \( 5r \) for linear molecules) give rise to lattice vibrations (frustrated translations and rotations) and to three acoustic modes. However, the internal vibrations
of each molecules should in principle give rise to \( r \)-fold splitting, as a result of the coupling of the vibrations within its primitive unit cell as a whole.

The analysis of the symmetry of the chemical species under study (i.e. the point group for a free molecule, or the space and factor groups for a crystal\(^{131} \)), according to the site symmetry of every atom, allows the determination of the irreducible representation of the total modes. After subtraction of the translational and rotational modes (the acoustic modes for the crystals), the irreducible representation of the vibrational (or optical) modes can be obtained. This means that the number of vibrational modes belonging to the symmetry species associated with the molecular or crystal symmetry can be counted. Consequently, the number of active modes can be counted, according to the symmetry selection rules of the different techniques (in particular IR and Raman).

In principle, every vibrational mode is due to motions of the chemical species (the molecule or the primitive unit cell) as a whole. Thus, molecular and crystal dynamics calculations should rigorously define the motion of every atom of the chemical species in terms of vibrational modes. For large and complex chemical species, this approach gives rise to a very complex picture so that the results are sometimes not easily interpreted and comparison between the vibrational behavior of similar species is frequently difficult.

However, a group approximation can be frequently used, in which the vibrational modes can be attributed approximately to the movements of small groups of atoms. This is especially the case if very different bonds are present in the molecule, so that the coupling of their movements is negligible. In this way, it is possible to dissect the chemical species under study and consider separately the vibrations of groups of a few atoms (such as the functional groups in organic compounds). This makes possible a satisfactory, although approximate, interpretation of the vibrational spectra of polyatomic molecules and of some crystals, and allows easy comparison between the vibrational features of related chemical species.

In the case of crystalline solids, more than one equivalent structural unit may be present in the primitive cell. This results in splittings of the fundamental vibrational modes of these units. In the case of many crystalline solid materials covalent units (e.g. oxo anions for oxo salts) are present, together with other groups bonded by ionic bonds (e.g. the cations in the oxo salts). According to the group approximation, the internal vibrations of the covalent units can be considered separately from their external vibrations (hindered rotations and translations of the group that finally contribute to the lattice vibrations and to the acoustic modes of the unit cell) and those of the other units. If a number of covalent structural units are present in the primitive cell, their internal modes become split.

In the spectra of solids, the polar phonons (those that are IR active) split into two components, the transverse optical (TO) mode and the longitudinal optical (LO) mode. This is because the electric field associated with the transverse wave is zero, whereas that associated with the longitudinal wave is nonzero; when coupling of these modes occurs with the electric fields associated with the vibration, this gives rise to the separation \( \nu_{\text{LO}} > \nu_{\text{TO}} \). This factor is relevant to the shape and interpretation of the IR spectra of solid materials, as discussed below.

### 2.3 Amorphous Solids

Amorphous solids differ from crystalline solids because no long-range order occurs. So, variable coupling exists between the vibrational modes of similar or equivalent structural units. Consequently, amorphous solids can be treated like liquids and gases. The vibrational spectra of amorphous materials can present a smaller number of broader features than those of corresponding crystalline materials, whereas crystal coupling effects can produce multiple sharp features. An example of this is treated below in some detail, concerning the forms of silica.

### 3 INFRARED SPECTROSCOPY OF INORGANIC SOLIDS

As already mentioned, a variety of IR techniques are in use to give information on the structure of different solids. When electromagnetic radiation is incident on a sample, the light may (essentially) be absorbed, reflected, or transmitted. Equation (1) follows from the conservation of energy:

\[
I_0 = I_R + I_T + I_A
\]

where \( I_0, I_R, I_T, \) and \( I_A \) are the intensities of the incident, reflected, transmitted, and absorbed radiation, respectively. Dividing Equation (1) by \( I_0 \) gives Equation (2):

\[
R + T + A = 1
\]

where \( R = I_R/I_0, \) \( T = I_T/I_0, \) and \( A = I_A/I_0 \) are the apparent reflectance, transmittance, and absorbance, respectively. In any IR technique, two selection rules are valid. They are simplified as follows:

\[
\Delta \nu = \pm 1
\]

\[
\left( \frac{\partial \mu}{\partial \mathbf{Q}} \right)_0 \neq 0
\]

Equation (3), where \( \nu \) is the vibrational quantum number, means that only transitions between nearest
vibrational states can directly occur in the case of the harmonic oscillator. However, this condition is relaxed in the case of anharmonic oscillators, so that not only fundamentals but also overtones and combination modes can sometimes be observed, although they are usually weak. Equation (4) indicates that only vibrational modes associated with a change in the dipole moment $\mu$ of the molecule between the extremes of the atomic displacements ($Q$ is the normal coordinate) different from zero can be directly excited. According to the Lambert–Beer law (Equation 5):

$$A = -\log_{10} \frac{I_T}{I_0} = \varepsilon c l$$

the absorbance $A$ linearly depends on the molar concentration $c$ of the absorbing species, through the molar absorption coefficient $\varepsilon$ and the sample path length $l$. This relationship (which is rigorously valid only in non-scattering media) is the basis for quantitative analysis performed through FTIR spectrosopies. Recent work has shown how to extend the range of Beer’s law in FTIR (Fourier transform infrared) spectrometry.\(^9\)

However, the absorbance at a particular wavelength also depends upon the population of the corresponding vibrational states. According to Boltzman’s law, Equation (6),

$$\frac{N_i}{N_0} = \frac{g_i}{g_0} e^{-\Delta E/kT}$$

where $N_i$ are the state populations and $g_i$ are the state multiplicities, $\Delta E$ is the energy difference between the states 0 and $i$ and $k$ is the Boltzmann constant. The $\Delta E$ values for fundamental vibrational transitions fall in the IR region, so that the population of the first excited states is very small at room temperature and lower than the population of the ground state even at 1000 K. This means that only transitions originating from the ground state can be ordinarily excited at room or relatively low temperature.

Commercial FTIR spectrometers, available at moderate costs, offer short recording times (one to a few minutes at most), high resolution (0.5–4 cm$^{-1}$) and are capable of obtaining desirable signal-to-noise ratios for most types of sample. These performances fulfill the requirements for the study of inorganic materials, in relation to the intrinsic line width of their modes (generally some tens of wavenumbers) and the optical properties of the samples. The different experimental set-ups are described below.

### 3.1 Transmission–Absorption Technique

This technique was originally applied by the pioneers of IR and is probably still the most widely used, even though its application to solids involves problems of sample form and preparation. Working with monocrystals or large particles is difficult, due to the high amount of absorbing species necessarily placed in the IR beam. However, this technique can be successfully applied to powdered materials, even though a problem arises from the radiation scattering.

When a radiation is incident on a nonabsorbing layer consisting of $N$ particles per unit volume, its intensity decreases exponentially with the sample thickness $x$, following Equation (7):

$$I_T = I_0 e^{-\phi x} = I_0 e^{-N\sigma x}$$

Thus an apparent absorbance $A'$ can be defined (Equation 8) for an absorbing and scattering medium:

$$A' = -\log_{10} \frac{I_T}{I_0} = 0.43 N\sigma x = 0.43 N(\varepsilon' + s)x$$

$$= A + 0.43 N\sigma x = A + S'$$

where $\phi$ is the linear attenuation coefficient and $\sigma$ is the linear attenuation coefficient of one particle. The coefficient $\sigma$ contains a component due to absorption, $\varepsilon'$, and a component due to scattering, $s$. So the apparent absorbance is composed of the true absorbance $A$ superimposed upon the component due to the light scattering $S'$. This simplified approach is similar to that given by Henry\(^10\) who proposed Equation (9) for the component dependent on scattering:

$$S' = kx d \frac{(n-1)^2}{\lambda^2}$$

where $k$ is a constant independent of $\lambda$ but dependent on the particle arrangement, $d$ is the particle diameter and $n$ is the refraction index of the material. However, according to the Rayleigh theory, $S'$ depends on the third power of the particle diameter (and so linearly on the particle volume) and on the fourth power of the radiation frequency $v$. Studies of effect of scattering on the IR transmission spectra of powder samples\(^11,12\) have shown that if the particle diameter is sufficiently small (considerably smaller than the IR wavelength), the scattering of the IR radiation is very small. Thus, finally, the apparent absorbance of a layer of a powder depends on its own absorptivity, on the disk thickness and density, on the particle size, and on the wavelength.

To obtain a good quality powder sample for the transmission–absorption IR technique, it is necessary to prepare a layer appropriately diluted and sufficiently thin. The most used technique uses KBr pressed disks. KBr is an easily available powdered material which is not absorbing in the medium IR region (down to near
The preparation of disks with polyethylene (which is transparent in most of the FIR region) is the most used technique. However, in this range the scattering is very soft, not hygroscopic. Silver bromide is sometimes possible to simply deposit the powder on a disk of a transmitting medium.

Another technique, used mostly in the past, is to mull the powder with organic liquids, such as liquid paraffin (nujol) and perhalogenated organics. The powder is mixed to make a paste from which a layer is formed. Absorptions from the mulling liquid (i.e. in the C–H stretching and deformation regions for paraffin oils, or C–X modes for halocarbons) also occur and obscure some spectral regions.

### 3.2 Reflection Techniques

When incident radiation interacts with a flat surface, the reflectances of the parallel and perpendicular polarized light with respect to the incidence plane, $R_p$ and $R_s$, are given by Equations (10) and (11):

$$R_p = \frac{\varepsilon \cos \theta - \sqrt{\varepsilon - \sin^2 \theta}}{\varepsilon \cos \theta + \sqrt{\varepsilon - \sin^2 \theta}}^2$$  \hspace{1cm} (10)

$$R_s = \frac{\cos \theta - \sqrt{\varepsilon - \sin^2 \theta}}{\cos \theta + \sqrt{\varepsilon - \sin^2 \theta}}^2$$  \hspace{1cm} (11)

where $\varepsilon$ is the complex dielectric constant of the material (assumed to be isotropic) and $\theta$ is the incidence angle. From these relationships it follows that the reflected light is mainly polarized perpendicular ($R_s$ is large, whereas $R_p$ has a minimum for $0 < \theta < 90\degree$). When $\theta = 0$, substituting $\varepsilon = (n - ik)^2$ gives Equation (12):

$$R = \frac{(n - 1)^2 + k^2}{(n + 1)^2 + k^2}$$  \hspace{1cm} (12)

where $n$ and $k$ are the real and imaginary parts of the absolute index of refraction. For conducting materials, such as metals, the refraction index is totally imaginary, which means that $n = 0$ so that $R = 1$ at any frequency, and the radiation is totally reflected. This is the case of total (or specular) reflection.

For insulating or weakly semiconducting materials, such as most inorganic compounds, $k = 0$ and $n$ is nearly constant (i.e. the index of refraction is real) in the IR spectrum except near the absorption frequencies, i.e. for $\nu > \nu_{LO}$ and $\nu < \nu_{TO}$. This means that outside of the latter skeletal region, monocrystal surfaces of inorganic compounds only weakly reflect the radiation, $R$ being smaller with greater $n$. This means that all light is essentially transmitted or, better, refracted. However, for $\nu_{LO} > \nu > \nu_{TO}$, the index of refraction is imaginary and $k > 0$ goes through a maximum. This means that near the skeletal absorption region, $R$ again becomes

400 cm⁻¹, i.e. it cuts out the FIR. It can be easily mixed homogeneously with the powder to be investigated, and pressed, thus obtaining diluted self-supporting disks very useful for IR transmission. The spectra so obtained give rise to a baseline due to scattering that gives very high transmission in the low-frequency region (down to the cut-off near 400 cm⁻¹ due to absorption by KBr itself). Other materials (see Table 1) give similar pressed disks, with cut-off limits at even lower frequencies, but are more expensive. Alternatively, the powders can be simply deposited in the form of a thin layer on a disk of a transmitting medium.

As KBr and the other alkali halides absorb in the FIR region, other binding materials must be used. The preparation of disks with polyethylene (which is transparent in most of the FIR region) is the most used technique. However, in this range the scattering is very low because of the long wavelengths involved, so that it is sometimes possible to simply deposit the powder on a disk of a transmitting material (see Table 1) using a solvent that later evaporates.

Another technique, used mostly in the past, is to mull the powder with organic liquids, such as liquid paraffin (nujol) and perhalogenated organics. The powder is mixed to make a paste from which a layer is formed. Absorptions from the mulling liquid (i.e. in the C–H stretching and deformation regions for paraffin oils, or C–X modes for halocarbons) also occur and obscure some spectral regions.
near to 1, i.e. the skeletal vibrations of inorganic compounds give rise not only to absorbed radiation in transmission experiments but also to reflected radiation in the reflection experiments (the reststrahlen effect). Thus, the specular reflectance for insulating materials, both in the form of monocrystals\(^5\) and in the form of sintered pellets,\(^13\) is frequently the basis for the best determination of the skeletal spectrum, as far as the IR-active modes are concerned.

Figure 1 shows the reflection spectrum of an MgO monocrystal compared with the transmission–absorption spectrum of MgO powder. MgO (periclase) has the rock-salt structure (space group \(Fm\bar{3}m\), with \(Z = 4\), and with one formula unit only in the smallest Bravais cell). The six degrees of freedom associated with the two atoms in the primitive cell give rise to a triply degenerate acoustic mode and to a triply degenerate optical mode. The irreducible representation for the optical modes is given by Equation (13):

\[
\Gamma_{\text{opt}} = F_{1u}(\text{IR})
\]  

Thus, rock-salt-type compounds are Raman-silent (as far as the fundamentals are concerned, see below) and only show one IR-active fundamental mode. The TO quoted for MgO at 401 cm\(^{-1}\) (Figure 1, curve a) corresponds to the lower frequency limit of the reflectance band, whereas the LO corresponds to the higher-energy limit of the reflectance, and is quoted at 718 cm\(^{-1}\).

For \(v_{\text{LO}} > v > v_{\text{TO}}\) the reflectance is strong and almost constant, but outside these limits the reflectance is very small. The transmission–absorption IR spectrum of the MgO powder shows the maximum slightly above \(v_{\text{TO}}\) (407 cm\(^{-1}\) in the spectrum of a polyethylene disk) and a shoulder near \(v_{\text{LO}}\). Other components arise from particles with different morphologies\(^14\) although it has been shown that the microcrystal powder spectrum of MgO is also affected by surface relaxation.\(^15\)

The total reflection of IR incident light at any wavelength from a surface can occur in two cases: (a) when the beam arises from a transmitting medium and is incident on the surface of a conducting material; and (b) when the beam arises and is incident within a transmitting medium, but the medium from which the beam arises has a higher refraction index than the other, and the incidence angle is greater than the limit for refraction.

It has been recognized in the first case that if molecules are adsorbed on the surface of a metal, only part of the grazing incident radiation is reflected, with part being absorbed by the adsorbed species. This absorption is greatly increased if the incident radiation is polarized perpendicular to the metal surface. This is infrared reflection absorption spectroscopy (IRRAS) which, mainly after the work of Greenler\(^{16}\) and Pritchard,\(^{17}\) is applied widely to surface studies on metal surfaces. Under these conditions, the additional selection rule of Equation (14)
applies:
\[
\left( \frac{\partial Q}{\partial Q} \right)_0 \neq 0
\]
(14)
which means that only the adsorbate vibrations associated with a change in the dipole moment perpendicular to the crystal surface are detectable. The total reflection technique can be applied to detect the growth of oxidic layers over metal surfaces (i.e. the skeletal bands of the oxide layers) and this is a widely applied technique in corrosion and electrochemical research.\(^{18,19}\) Colloid chemistry,\(^{20}\) coating technology,\(^{21}\) and heterogeneous catalysis.\(^{16,17}\)

The second case is internal reflection spectroscopy, utilized in attenuated total reflection (ATR)\(^{22}\) where an absorbing layer is deposited on one or two external surfaces of a prism. The light penetrates the prism from a free surface and is multiply reflected by the other faces. During the reflection, part of the light penetrates the external layer and is absorbed by it. Thus, in the case of the internal reflection technique the reflectance is given by Equation (15):
\[
R = 1 - A = 1 - \varepsilon cd
\]
(15)
where \(d\) is the thickness of the layer penetrated by the radiation, \(\varepsilon\) is the molar concentration of the absorbing species in that layer, and \(c\) is the molar absorption coefficient of that species. This technique has found application in the examination of several bulk solids (e.g. polymers\(^{23,24}\)), electronic devices (e.g. those constituted by silica layers on silicon\(^{25,26}\)), and glasses.\(^{27}\) This technique can also be applied to metal layers at the interface with a solution and in this case the signal can be surface enhanced.\(^{28}\) This technique is of wide interest in the fields of electrochemistry\(^{29}\) and colloid chemistry.\(^{30}\) An interesting variation is cylindrical internal reflection (CIR)\(^{31–35}\) As an example of use, a hydrogel slurry can be analyzed using cylindrical crystals immersed in the medium so that IR radiation is multiply transmitted and reflected at the internal surface. This technique could be successfully applied to heterogeneous catalytic systems at the water/solid interface, or in stages of catalyst preparation (e.g. zeolite syntheses).

Another interesting variant of the total reflection technique is surface electromagnetic wave spectroscopy (SEWS), which consists in the generation of a surface plasmon on a substrate by frustrated total internal reflection in a prism located a few micrometers from the surface. This plasmon is decoupled by a second prism. Some interesting results have been reported with this technique concerning surface species on alumina.\(^{34}\)

### 3.3 Diffuse Reflectance

The IR spectroscopy of powders in the diffuse reflectance mode has grown strongly, aided by the commercialization of appropriate attachments and cells. This technique is particularly attractive because it does not require much sample preparation (the powder is simply deposited in a sample holder). As this technique takes advantage of light scattering, it is very useful for studies in surface chemistry.

This technique requires collection of the radiation scattered by the sample with appropriate collecting mirrors, such as an integrating sphere. Most photons are essentially simply scattered, but those corresponding to the energies of vibrational transitions are potentially absorbed. The interpretation of diffuse reflectance spectra is based on the phenomenological theory of Kubelka and Munk.\(^{35–37}\) The Kubelka–Munk (K–M) function is given by Equation (16):
\[
f(R_\infty) = \frac{(1 - R_\infty)}{2R_\infty} = \frac{k}{s}
\]
(16)
where \(R_\infty\) is the reflectance of an infinitely thick layer and may in practice be substituted by \(R_\infty - R'_\infty\) (i.e. by the reflectance spectrum from which the reflectance of a transparent reference material such as KBr has been subtracted). The K–M function depends linearly on the absorption coefficient \(k\) (such that \(k = 2303\varepsilon c\), where \(\varepsilon\) is the molar absorption coefficient and \(c\) is the molar concentration) and inversely on the scattering factor \(s\). Obviously, the greater the absorption coefficient and the smaller the scattering, the higher the K–M function. An approximation of the K–M function is that \(k\) is treated as a variable but \(s\) is assumed constant. This is not true in the vicinity of strong absorptions.

More realistic and complex theories have subsequently been developed,\(^{38–41}\) according to the quite complex nature of the phenomena involved in the diffuse reflectance of light. Experimental studies\(^{42–45}\) showed that this technique is affected by particle size, granulometric distribution, and the index of refraction of the particles; the latter has an important role when the particle size is near the wavelength of the IR radiation. Diffuse reflectance infrared Fourier transform (DRIFT) studies in the FIR region allow the detection of the skeletal spectra of materials, such as mixed oxide catalysts, pigments, metal halides.\(^{46}\)

One important practical problem in diffuse reflectance measurement is the need to cancel the specular reflectance by the front surface of the sample, which generates negative bands in the DRIFT spectrum, so causing apparent shifts in the true absorption bands. This is achieved by using appropriate cell designs in commercial DRIFT attachments (see Figure 2).\(^{47,48}\)
3.4 Emission Technique

According to Kirchhoff’s law (Equation 17),

\[ \varepsilon = \frac{I_{em}}{I_b} = \alpha \]  

(17)

the emittance \( \varepsilon \) (i.e. the ratio of the light emitted by the sample \( I_{em} \) with respect to that emitted by a blackbody at the same temperature, \( I_b \)) is equal to the absorptance, \( \alpha \), of the sample. The emissivity is proportional to the fourth power of the temperature difference between the emitting sample and the detector (Stefan’s law). This implies that emissivity is sufficiently strong at relatively high temperatures to give a good signal-to-noise ratio in a large part of the IR spectrum. In fact, the blackbody emission below 1000 K shows its maximum in the medium IR region. According to Koenig, temperatures well above 500°C are needed to have a sufficiently good signal-to-noise ratio in the CH stretching region near 3000 cm\(^{-1}\).

A number of problems arise in connection with the use of infrared emission spectroscopy (IRES). One of them arises from the existence of temperature gradients that can cause self-absorption of the emitted radiation by the colder outer parts of the sample itself; another is concerned with selective reflection that occurs in the vicinity of strong absorption bands. This reduces the absorptance and hence the emittance. Moreover, perturbations can be created by reflections and emission by the cell elements. However, these problems can in part be overcome so that IRES can be successfully used in the fields of polymers and corrosion science. The IRES of metal oxides in the field of surface chemistry and catalysis has been reviewed recently by Sullivan et al. These authors reported several examples of emission spectra of oxide catalysts and of adsorbates on supported metals, and cite at least 11 papers concerning metal oxide surfaces. Some of the advantages of this technique are the very easy sample preparation and its easy applicability at high temperatures (150–400°C). It can be applied to investigate the temperature dependence of the radiative properties of materials, such as glasses.

3.5 Photoacoustic and Photothermal Techniques

When an IR beam is incident on a solid surface it can be absorbed in part, and this leads to its conversion into heat. If the beam is modulated (as in any interferometers such as those of FTIR instruments) and the solid is in contact with a gas (air, He, Ar, . . . ), its conversion
to heat gives rise to an acoustic signal. In fact, the periodic temperature rise so obtained causes a periodic modulation of a gas pressure in the cell that can be detected by a sensitive microphone (Figure 4). This acoustic signal will be the more intense the stronger is the absorption at a particular wavelength. Reflected and scattered light are not absorbed and hence do not cause a photoacoustic signal. However, light absorbed by the gas over the sample causes signals. This makes necessary the use of monoatomic nonabsorbing gases (He, Ar, . . . ). The photoacoustic effect, discovered as early as in 1880 by Bell, could be successfully applied essentially only after the work of Rosencwaig and Gersho in 1976. The main limitations of this technique are: (a) it requires a gaseous atmosphere; (b) the cell needs a microphone close to the sample (see Figure 7) so the sample cannot be heated and otherwise activated conveniently; and (c) the technique has an intrinsically low signal-to-noise ratio. However, the photothermal effect is much more efficient for species in the vapor phase than for bulk and surface species. Photothermal spectroscopy (PAS) is not exactly a surface spectroscopy, because the penetration of the thermal effect is always significant. The extent of this depends on the modulation frequency, which varies with wavenumber in a Fourier transform (FT) spectrum. The PAS technique has found successful applications in polymer science, surface carbon studies and coal characterization, and in heterogeneous catalysis.

Another technique is photothermal beam deflection spectroscopy (PBDS), based on the mirage effect first reported by Boccarra et al. and developed in the IR region by Low et al. In this case, the periodic temperature rise caused by the absorption of the modulated IR radiation (i.e. the photothermal effect) is detected optically because it causes periodic deflections of a laser beam passing close to the surface of the sample (Figure 5). The PBDS technique has some advantages over PAS because of its lower limits of sample dimensions, but has disadvantages because of the critical geometric set-up. As for PAS, PBDS can have advantages with respect to traditional IR for the detection of surface vibrations in very opaque materials. This has resulted in the application of PBDS to carbons and coals.

### 4 RAMAN SPECTROSCOPY OF INORGANIC SOLIDS

The Raman effect is based on the inelastic scattering of electromagnetic radiation by molecular vibrations. When the radiation is incident on a sample, some photons are scattered due to the dipole moments induced through the static polarizability of the electrons. This is Rayleigh or elastic scattering. However, a small number of photons are scattered through modulation of the polarizability by electronic, vibrational, or rotational motion, leading to Raman or inelastic scattering.

Using a simple classical model it is easy to demonstrate that when a chemical species is irradiated at the frequency \( v_0 \) and its polarizability is modulated at the vibrational frequency \( v_1 \), the time dependence of the induced dipole moment \( \mu \) is given by Equation (18),

\[
\mu(t) = \alpha_0 E_0 \cos 2\pi v_0 t + \frac{1}{2} \left( \frac{\partial \alpha}{\partial Q} \right)_0 Q_0 E_0 \cos 2\pi (v_0 + v_1) t + \frac{1}{2} \left( \frac{\partial \alpha}{\partial Q} \right)_0 Q_0 E_0 \cos 2\pi (v_0 - v_1) t
\]

where \( \alpha \) is the polarizability, which is a function of the normal coordinate \( Q \) in a Taylor’s series expansion.
INFRARED SPECTROSCOPY

Figure 6 FTIR transmission–absorption spectrum (KBr and polyethylene disks, broken line) and FT/Raman spectrum (full line) of a commercial TiO$_2$ anatase powder. (Reproduced with permission from G. Busca, Catal. Today, 27, 323–352 (1996).)

(Equation 19):

$$\alpha = \alpha_0 + \left( \frac{\partial \alpha}{\partial Q} \right)_0 Q + \frac{1}{2} \left( \frac{\partial^2 \alpha}{\partial Q^2} \right)_0 Q^2 + \cdots \tag{19}$$

where $\alpha_0$ is the static polarizability and $E_0$ is the amplitude of the radiation. The three terms in Equation (18) correspond to Rayleigh scattering (with $v = v_0$), to anti-Stokes–Raman scattering (with $v = v_0 + v_1$) and to Stokes–Raman scattering (with $v = v_0 - v_1$), respectively. From a quantum-mechanical treatment it is possible to rationalize why anti-Stokes–Raman scattering is far weaker than Stokes–Raman scattering, in particular for high frequency modes.

It is possible to conclude that Raman scattering occurs only if Equations (20) and (21) hold:

$$\Delta v = \pm 1 \tag{20}$$

$$\left( \frac{\partial \alpha}{\partial Q} \right)_0 \neq 0 \tag{21}$$

This also means that in Raman spectroscopy only transitions between nearest levels and those associated with changes in the polarizability $\alpha$ upon motion are allowed for a harmonic oscillator. The first selection rule is relaxed for anharmonic oscillators. Group theory shows that for centrosymmetric chemical species Raman-active modes are IR inactive, and vice versa. This is the mutual-exclusion rule. Other modes can be both IR and Raman inactive. For noncentrosymmetric molecular species, modes also occur that are both IR and Raman active.

The Raman scattering process is inherently weak (only a small fraction of photons are scattered, about $10^{-6}$) and this limit is expected to be even more important for surface species. The intensity of the Raman signal of adsorbed species can be enhanced by surface-enhanced Raman scattering (SERS) that is, however, limited to rough surfaces of a few highly reflective metals.$^{66,67}$

Raman spectroscopy of inorganic materials offers advantages over IR spectroscopy because of the weak Raman scattering intensity from the skeletal vibrations of ionic oxides and (generally) the absence of TO/LO splitting, offering rather high resolution, and high spatial resolution allowing microspectroscopy. As an example, the FTIR and FT/Raman skeletal spectra of a TiO$_2$ anatase powder sample are compared in Figure 6.

One of the problems with Raman spectroscopy is the superimposition of the Raman effect by fluorescence phenomena. To avoid this, FT/Raman spectrometers working with NIR lasers have been developed. Alternatively, anti-Stokes–Raman spectrometry may be used in spite of the weakness of the anti-Stokes–Raman signal.$^{68}$

5 INELASTIC NEUTRON SCATTERING SPECTROSCOPY

Among the techniques based on the inelastic scattering of particles, the INS techniques allow important data to be obtained for the vibrational characterization of solids. The INS technique$^{69,70}$ consists of the analysis of the energy distribution among neutrons inelastically scattered by the chemical species under study, generally presented in a dispersed form such as in the form of powders. If the instruments operate with a polychromatic continuous
neutron source (from a fission nuclear reactor), the dispersion of the scattered beam is obtained before the sample by Bragg reflection from a single crystal operating as a diffraction monochromator.

However, if the instrument works with a pulsed neutron beam (spallation source) the energy analysis is obtained by using the time-of-flight technique, i.e. by measuring the time of arrival at the detector of the scattered neutrons after the pulse, through the source–sample–detector route. This arrangement is shown in Figure 7.

The INS technique has many disadvantages with respect to the much easier IR technique, essentially associated with the limited availability of a neutron beam source, the complexity of the neutron energy dispersion, and the neutron detection complexities. Moreover, the resolution is much smaller (near 2% of the energy transfer, which means 20 cm$^{-1}$ at 1000 cm$^{-1}$); to increase the signal-to-noise ratio the spectra are usually recorded at very low temperatures.

In principle, there is a great advantage of INS with respect to both IR and Raman spectroscopies, because there are no selection rules and so all vibrational transitions are in principle INS active. However, the intensity of the INS peaks depends on the INS cross-section of all the atoms involved in the corresponding vibrational mode. This cross-section is characteristic of each element and does not depend on its chemical environment; it is at least 40 times greater for hydrogen than for any other element. Thus, the peaks associated with modes that involve hydrogen motions dominate the spectra, whereas those that do not involve hydrogen motions can be so weak as to be undetectable.

It is evident that INS spectra are particularly useful for the detection of vibrational transitions involving hydrogen-containing species and hydroxy groups. This is particularly true for the vibrational transitions associated with adsorbed hydrocarbons, hydroxyls and water on zeolites and of hydrogen and absorbed species adsorbed on metallic catalysts (the latter, when unsupported, cannot be studied by IR and Raman), as well as hydride species on oxide and sulfide catalysts. In the latter cases, these absorptions can fall into the region below 1000 cm$^{-1}$, where metal–oxygen and metal–sulfur skeletal vibrations occur and dominate IR and Raman spectra. As the skeletal vibrations of oxides and sulfides are very weak in INS spectra, those involving hydrogen are detected easily. This technique has been applied successfully to the analysis of hydrogen bonds in solids, such as the analysis of hydrogen bonds in metal hydroxides including iron oxyhydroxides, the free proton dynamics in $\gamma$-MnO$_2$, and hydrogen bonding in ices. Low-energy vibrational modes in oxides have also been studied.

6 APPLICATIONS OF VIBRATIONAL SPECTROSCOPIES TO THE CHARACTERIZATION OF INORGANIC SOLIDS

Several collections of IR, Raman, or both IR and Raman spectra of inorganic materials and minerals have been published and are available electronically. The following discussion briefly reviews some of the
applications of vibrational spectroscopies in the fields of characterization of such materials. A database of standard Raman spectra of minerals and related inorganic crystals has been published.\(^{88}\)

### 6.1 Simple Anhydrous Oxides

Within basic inorganic chemistry\(^ {87-89}\) the oxides of nonmetals are defined as acidic oxides or anhydrides, whereas the oxides of metals are denoted as basic oxides. Some oxides have both acidic and basic character and are consequently defined as amphoteric. The bulk properties of these compounds are related to their crystal chemical features and are also reflected in their bulk vibrational properties.

#### 6.1.1 Ionic/Covalent Nature of Solid Oxides and Their Vibrational Features

The oxides of low-valency metals (i.e., with cations of oxidation number \(\leq +4\)) are typically ionic compounds. They are most frequently easily obtained in crystalline forms.

For sufficiently small cations \((r < 0.8 \, \text{Å})\) the oxide structures are determined by cubic or hexagonal close packing of oxide ions with the cations in tetrahedral or octahedral interstices.\(^ {90-93}\) Bigger cations do not enter such interstices, so that structures with less densely packed oxide ions (e.g., simple cubic) and higher coordinations for the cations must occur (seven or eight). In ionic metal oxides coordination of the cations (four to eight) is generally higher than the valency (one to four) and this also occurs for the coordination of \(\text{O}^{2-}\) oxide ions (three to six).

The oxides of nonmetals are characterized by the considerable covalent nature of the bond between the nonmetal and oxygen, in agreement with the high electronegativity of the nonmetal elements. This frequently results in molecular structures for the nonmetal oxides, some of which are gaseous or liquid in normal conditions. Some form cyclic polymeric molecules and are solid in normal conditions (e.g., \(\text{Se}_2\text{O}_{12}, \text{P}_2\text{O}_{10}\)). By decreasing the element electronegativity, covalent network structures are formed for semimetal oxides (e.g., \(\text{B}_2\text{O}_3\) or \(\text{SiO}_2\) in their room-pressure forms). Although they can form crystalline phases, the solid oxides of semimetals are also characterized by the existence of very stable amorphous states and by their glass-forming properties.\(^ {94}\) These metastable amorphous or vitreous structures find many applications (e.g., for silica) and can be converted into stable crystalline phases at very high temperatures.

The covalent nature of the solid nonmetal oxides (molecular or network) is shown by the coordination around the element that either corresponds to its valency or is even lower. In such structures, the oxygen is either bridging between two metal atoms or bonded to one atom only with a former double bond.

The bulk acidity of these nonmetal solid oxides is associated with the acidity of the product of their reaction with water, giving an oxo acid. The acidity of oxo acids is associated with the strong covalency of the nonmetal–oxygen bond, which subtracts electronic charge from the oxygen atom thus allowing the O–H bond to be highly polarized and stabilizing the negative charge of the anion produced by dissociation. However, the acid strength of oxo acids is primarily enhanced by the presence of doubly bonded oxygen atoms around the nonmetal atom, which allows delocalization of the negative charge produced by the acid dissociation. For this reason, the higher the oxidation state of the nonmetal, the more the oxygen atoms are doubly bonded, and the stronger is the acidity of the oxo acid.

The oxides of the metal elements in very high oxidation states (e.g., Mn\(^{\text{VII}}, \text{Cr}^{\text{VI}}, \text{Mo}^{\text{VI}}, \text{W}^{\text{VI}}, \text{V}^{\text{V}}, \text{Nb}^{\text{V}}, \text{Ta}^{\text{V}}\)) are also frequently denoted as anhydrides, and give rise, by reaction with water, to acid species (sometimes polyoxoacids) that can be strongly acidic. Due to the high oxidation states of the metal elements in these compounds, their electronegativity is very high, \(^{95}\) so the oxides and the derived acids have nearly the same properties as those from nonmetal oxides and acids.

The structural properties of the compounds of metals in very high oxidation states \((\geq +5)\) differ from those of nonmetals, in that the coordination around the metal atom is elastic and can be very distorted. For example, the overall coordination of pentavalent vanadium\(^ {96}\) and hexavalent molybdenum in their oxides is frequently quite arbitrarily defined, and can vary from four to six depending on the environment. Sixfold coordination for these ions is frequently very distorted, with one or two very short metal–oxygen bonds and one or two very long so that, excluding the longest bonds, sixfold coordination frequently approaches fourfold coordination.\(^ {97}\)

In network oxide structures the metal–oxygen bonds are all almost equivalent, so that their movements couple extensively. Also, the stretching and deformation vibrations mix. As a result, assignments of the different vibration modes can be very approximate. However, the higher-frequency vibrational features are generally associated with stretching modes. The position of these modes can be assumed to be primarily dependent on the coordination of the involved metal ions and on the extent of the condensation of the resulting polyhedra (Table 2). This approach has been proposed by Tarté\(^ {98,99}\) and is a useful approximation for the interpretation of the IR and Raman skeletal spectra of oxides of unknown structure. However, and perhaps more correctly, analysis of the spectra suggests that the higher-frequency modes are
mainly to be assigned to motions of the lighter oxygen atoms, so that they can be assigned to stretchings of oxygen in different coordination states. This alternative approach, first proposed by Beattie and Gilson, \textsuperscript{100} is shown in Table 3.

Most simple oxide structures have been the object of extensive studies and complete vibrational analysis. Some examples are summarized in Table 4.

### 6.1.2 Silica

The different polymorphs of silica – α- and β-quartz, α- and β-cristobalite, tridymites, coesite, morganite, and silicalite – all have tetrahedrally coordinated silicon. Their vibrational structures, as well as that of amorphous or vitreous silica, represent vibrations of the basic structural units of both crystalline and amorphous silica, namely SiO$_4$ tetrahedra and bridging oxygens. Additional sharp peaks can be found in the IR and Raman spectra of crystalline polymorphs in the region below 700 cm$^{-1}$, which are associated with splittings of the above modes, due to crystal structure effects, and to torsional lattice modes.

The interpretation of the spectra of silica polymorphs can be attempted on the basis of a model assuming the bridging Si$_2$O$_4$ or T–O–T monomeric unit, as done by Bell and Dean\textsuperscript{103} and by Galeener\textsuperscript{104} for amorphous silica. This approach gives rise to a picture agreeing with that arising from the lattice dynamics calculations of van Santen et al.\textsuperscript{105,106}.

An oxygen atom in any tetrahedral-based SiO$_2$ polymorph or zeolite is bonded symmetrically with two tetrahedral cations (T) giving rise to a bent T–O–T group. Assuming that this group is symmetrical and isolated, the site symmetry of oxygen is $C_{2v}$. So, the three degrees of freedom of any oxygen atom consist of two in-plane movements ($A_1$ and $B_1$) and one out-of-plane movement ($B_2$). The $B_2$ movement is associated with the out-of-plane deformation of the T–O–T group, the $B_1$ with the asymmetric stretching, whereas the $A_1$ mode has the character of both a symmetric stretching and an in-plane bending mode (scissoring). According to this, the three main IR bands observed in all silica polymorphs are classically assigned to the asymmetric stretching (arising from the $A_1$ mode, $v_1$), to the in-plane bending (arising

In the antisymmetric stretching, a bending, and a rocking mode. In the tetrahedral silica network, i.e., a symmetric stretching, an asymmetric stretching mode mainly because the Raman peak intensity is generally greater for stretching than for bending modes. However, the coupling of this mode with the scissoring mode provides an explanation of the low frequency of the strongest Raman peak (550–350 cm⁻¹) in all silica polymorphs. It is also clear that in the solid state, in order for all T–O bonds to expand in phase, most T–O–T angles must contract simultaneously. This mode is consequently highly sensitive to the structure of the polymorph, as is indeed observed. The position of the strongest Raman peak, ν₄, in fact, strongly depends on the type of rings present in silicas and silicates, as shown by Sharma et al.,(108) and on the density of the unit cell, as shown by Kingma and Hemley for silicas,(102) This is shown in Table 5.

As for the IR spectrum, the strongest complex band is ν₁, observed in the 1300–950 cm⁻¹ region, and is associated with the asymmetric stretching of the T–O–T bridges. However, as recently pointed out by Kamitsos et al.,(109) this mode is split into two components even in the case of vitreous silica, due to either the in-phase (ν₁) or the out-of-phase coupling (ν₁⁻) of the asymmetric stretching modes of the nearest T–O–T groups. In other words, this mode couples with the symmetric and asymmetric stretching of the four Si–O bonds of the SiO₄ octahedra. As shown in Table 5, it seems clear that the position of both ν₁ and ν₁⁻ components is also somewhat

* Defect bands.
frequently present. They are associated with the splitting of these vibrational modes (bands above 350 cm\(^{-1}\)) or to torsional lattice modes (below 400 cm\(^{-1}\)).

Figure 8 compares the FTIR and FT/FIR transmission-absorption spectra of an amorphous silica sample (aerosil) and of a crystalline powder (\(\alpha\)-quartz). The \(v_1\), \(v_2\), and \(v_3\) absorptions (broad) are evident for amorphous silica. In the case of quartz, more, sharper components are observable, as expected: 10 maxima can be easily observed at 1165, 1086, 798, 779, 694, 519, 463, 397, 373, and 263 cm\(^{-1}\). The irreducible representation for \(\alpha\)-quartz (taking the right-handed enantiomorph with space group \(P\bar{3}21\), with \(Z = 3\)) is \(4A_1(R) + 4A_2(IR) + 8E(R,IR)\) so that 12 IR-active fundamental modes are expected, each one undergoing TO/LO splitting. In the \(v_1\) region (asymmetric Si–O–Si stretching) three fundamental modes are expected, so that in the maximum at 1086 cm\(^{-1}\), which shows shoulders on both sides, more components are superimposed. Three resolved components are found as expected in the \(v_2\) region. One fundamental mode is expected to be very weak near 130 cm\(^{-1}\), but could not be detected.

The difference between the network silicate structure of the silica and the layer silicate structure of kaolinite is mainly shown by the presence, in the case of kaolinite, of a strong band with maxima at 940 and 913 cm\(^{-1}\), typically due to Si–(OH) terminal stretchings. In this region silicas and network silicates do not absorb.

Another form of silica, called silicalite, belongs to the MFI IUPAC zeolite code, which belongs to the \(P2_1/n = C_{2h}^6\) monoclinic space group (number 14) with \(Z = 96\). It transforms into an orthorhombic structure, belonging to the \(Pnma = D_{2h}^{16}\) space group (number 62) between 350 and 363K. Substituted silicalites like ZSM5 zeolite (see below) and Ti-silicalite take the orthorhombic structure even at room temperature, the transition temperature being strongly shifted to lower temperatures.

The factor group analysis for monoclinic silicalite\(^{112}\) gives the following irreducible representation for the optical modes:

\[
\Gamma_{\text{opt}} = 216 A_g (R) + 216 B_g (R) + 215 A_u (IR) + 214 B_u (IR)
\]

For the orthorhombic structure the following irreducible representation is obtained:

\[
\Gamma_{\text{opt}} = 110 A_g (R) + 106 B_{1g} (R) + 110 B_{2g} (R) + 106 B_{3g} (R) + 106 A_u (inactive) + 109 B_{1u} (IR) + 105 B_{2u} (IR) + 109 B_{3u} (IR)
\]

Figure 8 FTIR and FT/FIR transmission spectra of amorphous silica (aerosil), \(\alpha\)-quartz and kaolinite powders (KBr and polyethylene disks).
Accordingly, 429 IR-active modes and 432 Raman-active modes are expected for the monoclinic structure and 323 IR-active modes and 432-Raman active modes are expected for the orthorhombic form. The maxima really observable for silicalite are reported, together with those of other silica polymorphs, in Table 5. We observed only 16 components in the IR spectrum and 11 components in the Raman spectrum, because of the superimposition of many of the expected fundamentals. However, careful observation of the spectra, with the help of analysis of the perturbations arising from isomorphic substitution and with the aid of derivative spectra, showed the presence of a great number of very weak components (shoulders) in the spectra.

6.2 Complex Oxides

There are many ways to combine oxide components, producing a so-called mixed oxide. They depend not only on the preparation procedure adopted, but also on the nature of the component oxides. We will summarize them here below.

6.2.1 Mixing of Ionic Oxides

Several pairs of ionic oxides with the same crystal structure present extended or total reciprocal solubility. In other cases only limited solubility occurs, mainly due to their too-different cationic size. Limited reciprocal solubilities are also found for oxides having different structures but the same stoichiometry. Very limited solubilities are frequently found for ionic oxides having different structures, because of the superimposition of many of the expected fundamentals. However, careful observation of the spectra, with the help of analysis of the perturbations arising from isomorphic substitution and with the aid of derivative spectra, showed the presence of a great number of very weak components (shoulders) in the spectra.

6.2.2 Mixing of Covalent Oxides

Covalent oxides can also give rise to more or less extended solid solutions (such as those of MoO3 and WO3) and compounds, which can be treated similarly to the pure covalent oxide structures; sometimes they are treated as mixed compounds. If the two cations are both sufficiently small, mixed oxide phases with oxide close pack structures (either hcp or ccp) are formed, with cations in tetrahedral or octahedral interstices. Spinel phases (formed by a bivalent and a trivalent metal in a 2:1 atomic ratio) and ilmenites (a bivalent and a tetravalent element in a 1:1 atomic ratio) are examples. Alternatively, one of the two cations can enter into oxide close packing, but the other can be too large, needing higher coordination numbers than six. This generates other structures such as the β-aluminas (a monovalent or a bivalent element with a trivalent element in ratios 1:17–1:19) and perovskites (two trivalent elements or one bivalent and one tetravalent in 1:1 atomic ratios).

From the point of view of vibrational spectroscopies, the treatment of such complex oxides does not differ significantly from those of the pure ionic oxides. Data on ternary oxide phases with the ABO3 stoichiometry are given in Table 6.

6.2.2 Mixing of Covalent Oxides

Covalent oxides can also give rise to more or less extended solid solutions (such as those of MoO3 and WO3) and compounds, which can be treated similarly to the pure covalent oxide structures; sometimes they are treated as the salts (see below).

6.2.3 Mixing of Covalent and Ionic Oxides: the Oxo Salts

Ionic and covalent oxides mostly give rise to ternary phases, known as oxo salts. Examples are metal silicates, phosphates, molybdates, tungstates, chromates, and vanadates. Their structures have little in common with those of the pure oxides. Frequently, different salts can be produced starting from the same oxide components, in relation to the different compositions, as for ortho-, pyro-, and meta-vanadates, silicates, and phosphates.

The oxo salts contain covalent structures (the oxo anions) ionically bonded to cations. This allows easy distinction of some vibrational modes involving the nonmetal atom (or the higher oxidation state metal) from those involving the metal atom.

6.3 Vibrational Features of Complex Oxides of Practical Interest

6.3.1 Cuprate Superconductors

Vibrational spectroscopies have largely been used to characterize these superconductor ceramics. However, most studies involve Raman spectroscopy and IR reflection measurements of monocrystals. Additionally, the interpretation of such measurements is mostly performed using lattice dynamics calculations. This approach, although very complete in principle, does not always give rise to a good fit between calculated and theoretical frequencies and does not allow easy comparison between the vibrational features of different structures. The interpretation of IR spectra of superconducting powders based on the group approximation has also been attempted. From these studies, some conclusions can be drawn allowing the comparison of the spectra of different superconducting cuprates:

- The highest frequency IR and Raman modes are due to stretchings of the basal Cu–O bonds.
- The position of the higher-frequency Cu–O asymmetric stretching mode easily correlates to the length of the basal Cu–O bonds.
- Loss of resolution for the individual components is typical for samples approaching the composition that allows superconductivity to occur at low temperature.
- Modes parallel to the Cu–O square planes are screened out when the structures become able to undergo the superconducting transition due to doping effects, such as for YBCO, Nd$_2$–Ce$_2$CuO$_4$, La$_2$–Ba$_x$CuO$_4$, and La$_2$–Sr$_x$CuO$_4$.

6.3.2 Ferrite Magnetic Materials

Many ferrimagnetic materials, used as magnetic pigments or as permanent magnets, belong to two classes of ferrites.

The soft ferrites are based on inverted spinel structures (Fe$_3$O$_4$, MnFe$_2$O$_4$, mixed (Mn,Zn)Fe$_2$O$_4$, MgFe$_2$O$_4$, CoFe$_2$O$_4$). The cubic spinel structure, irrespective of the cation distribution of normal, inverted or random spinels, belongs to the $O_h^6$ = Fd$ar{3}$m space group with Z = 8. Five Raman-active modes and four IR-active modes occur; both IR$^{119-121}$ and Raman spectroscopies$^{122,123}$ have been used to characterize such structures. Also the magnetic ferric oxide maghemite ($\gamma$-Fe$_2$O$_3$) can be assumed to belong to the same family although its distorted spinel-like structure is far more complex, and possibly still not defined with certainty. The IR$^{124}$ and Raman$^{123}$ spectra of $\gamma$-Fe$_2$O$_3$ are also definitely more complex than that of spinels, showing that the maghemite structure is actually a superstructure. The other class of ferrite materials is the hard ferrites. The best known example is barium ferrite, BaFe$_{12}$O$_{19}$, which takes the magneto-plumbite structure (space group P63/mmc = $D_{6h}^1$, with Z = 2) of PbFe$_{12}$O$_{19}$. IR studies have been devoted to barium ferrite magnetic materials, giving further information on the structure and the likely dynamic disorder involving one ferric atom between two sites, one located in a mirror plane and the other out of it.$^{124,125}$

6.3.3 $\beta$-Alumina-type Ionic Conductors

One of the most relevant families of ionic conductor solids are the so-called $\beta$-aluminas. The parent compound is sodium $\beta$-alumina whose composition (when stoichiometric) is NaAl$_{11}$O$_{17}$. Spectroscopic investigations have been devoted to this compound$^{126,127}$ as well as to other compounds of the same family.$^{124}$

These phases are characterized by the existence of layered blocks of a trivalent element (most frequently Al$^{3+}$, but also Fe$^{3+}$ and Ge$^{4+}$) with the same spinel structure separated by mirror planes. The big monovalent ion (Na or K), bivalent (Ba and sometimes Ca or Sr) and trivalent (La) cations, which do not enter the cubic close packed array of oxide ions of the spinel blocks, are located together with oxide anions bridging between the blocks. In these planes the cations are able to diffuse. The metal–oxygen stretchings involving such ions located in the mirror planes fall in the low-frequency (FIR) region. For this reason FIR and Raman spectroscopy have been devoted to studies of the coordination and mobility of such cations.$^{124,128,129}$

6.4 Metal Hydroxides

The solid crystalline hydroxides are generally formed from condensed polyhedra containing the metal element surrounded by oxygen atoms. The hydrogen atoms are located externally to the polymeric structures and are involved in hydrogen bonding. Thus the skeletal spectra of hydroxides show features typically arising from the OH
groups, and features to be assigned to the vibrations of MO$_3$ polyhedra. For the latter features, the considerations already made for oxides are valid.

The vibrations of hydroxy groups are typically composed of O–H stretchings (3800–2000 cm$^{-1}$, depending on the extent of hydrogen bonding), in-plane bending (1200–800 cm$^{-1}$), and out-of-plane deformation (generally below 1000 cm$^{-1}$). The multiplicity of such modes depends upon the number of hydroxy groups present in the smallest Bravais cell and in the coupling of their vibrations, and is also dependent on the hydrogen-bonding patterns.

The vibrational spectra of alkali metal hydroxides have been reviewed by Ryskin and Farmer.$^{130}$ The centrosymmetric structures of LiOH and NaOH, both containing two formula units per unit cell, give rise to two OH stretching modes, one of which is IR active and the other Raman active. In the case of KOH, whose structure is not centrosymmetric and again contains two formula units per unit cell, a split both of IR- and Raman-active peaks is detectable. The positions of these peaks (in the 3680–3600 cm$^{-1}$ region) show that no hydrogen bonding occurs in these structures.

The structure of brucite Mg(OH)$_2$ is assumed by most bivalent hydroxides. Every layer of Mg(OH)$_2$ contains MgO$_6$ octahedra with three triply-bridging hydroxy groups pointing up and three pointing down, alternately. The unit cell of the brucite structure contains only one Mg(OH)$_2$ unit, so 12 optical modes should exist. Two OH stretching modes exist, one Raman active (symmetric stretching, $A_{1g}$, 3655 cm$^{-1}$) and one IR active (asymmetric OH stretching, $A_{2u}$, 3700 cm$^{-1}$). The positions of these modes show that no hydrogen bonds occur in this structure. Additional two doubly-degenerate deformation modes occur, again one Raman active ($E_g$) and one IR active ($E_u$). Finally, two IR-active modes ($A_{2u}$ + $E_u$) and two Raman-active modes ($A_{1g}$ + $E_g$) are associated with vibrations of the MgO$_6$ octahedra. Lutz et al. compared the vibrational structures (IR, Raman, and INS) of several brucite-type hydroxides$^{131}$ as well as oxhydroxides of bivalent metals in the fundamental$^{132}$ and overtone regions.$^{133}$

The goethite or diaspore structures of $\alpha$-AlOOH, $\alpha$-FeOOH, $\alpha$-CrOOH and $\alpha$-GaOOH have orthorhombic unit cells, belonging to Pbmm = $D_{2h}^{12}$ = 62 space group with $Z = 4$. The overall unit cell and the smallest Bravais cell coincide and contain 16 atoms; thus 45 vibrational modes are expected. All atoms occupy the 4c Wyckoff position in the cell on a reflection plane (C$_2$ site symmetry). According to literature data,$^{134,135}$ and separating the modes due to the hydrogen-bonded OH groups from those of the Me–O skeleton, the irreducible representation for the IR optical modes of $\alpha$-MeOOH is as follows:

$$\Gamma_{\text{Me–O}} = 5B_{1u} \text{ (IR)} + 2B_{2g} \text{ (IR)} + 5B_{3u} \text{ (IR)}$$

$$\Gamma_{\text{O–H}} = 2B_{1u} \text{ (IR)} + 1B_{2g} \text{ (IR)} + 2B_{3u} \text{ (IR)}$$

Consequently, the IR spectrum is expected to contain 17 fundamental modes. Clearly, not all will be resolved. A typical feature of the spectra of these compounds is the presence of two IR-active OH stretchings, giving rise to a strong band with a shoulder at the higher frequency in the IR spectra (3126 and 3050 cm$^{-1}$ for goethite, 3000 and 2920 cm$^{-1}$ for diaspore, and 2913 and 2840 cm$^{-1}$ for $\alpha$-GaOOH) as well as two strong bending modes (891 and 796 cm$^{-1}$ for goethite, 1080 and 970 cm$^{-1}$ for diaspore, and 1019 and 952 cm$^{-1}$ for $\alpha$-GaOOH), which have been discussed in terms of the geometry of the hydrogen-bonding situations. The materials $\alpha$-(Cr,Fe)OOH$^{136}$ and $\alpha$-(Fe,Ga)OOH,$^{137}$ forming goethite-type solid solutions, have also been characterized by IR. The INS spectra of goethite have also been reported.$^{17}$

X-ray diffraction (XRD) analysis indicates that boehmite $\gamma$-AlOOH and lepidocrocite $\gamma$-FeOOH crystallize in the space group $Cmcm = D_{2h}^{17}$, i.e. space group 63 with Z = 4. However, XRD analysis does not reveal the position of the hydrogen atoms. To obtain information on the position of the hydrogen atoms, vibrational spectroscopies can be used. The IR spectra are dominated by two well-split OH stretchings at 3295 and 3090 cm$^{-1}$ for boehmite and at 3390 and 3125 cm$^{-1}$ for lepidocrocite. Some authors have concluded that the IR spectra of boehmite, in particular the modes associated with the vibrations of the hydroxy groups, are consistent with the space group $Cmcm$, whereas others have concluded that a lower symmetry space group applies, namely $Cmc2_1 = C_{2h}^{12}$ of space group 36.$^{139}$ Publication of the Raman spectrum by Kiss et al.$^{140}$ confirmed that the mutual exclusion rule applies, so the noncentrosymmetric space group $Cmc2_1$ must be ruled out, the true space group for boehmite being $Cmcm$.

More recently, boehmite spectra have been compared with those of samples containing small amounts of silica.$^{141}$ Three different behaviors for the IR bands of boehmite upon Si addition can be noticed: (a) some bands are essentially not perturbed or are only slightly shifted by silicon addition; (b) other bands progressively decrease in intensity; and (c) others are eliminated even with a very small amount of silica addition. In particular, the bands lost through silicon addition are those at 325, 398, 412, 1161, 3088 and 3305 cm$^{-1}$, i.e. bands associated with the vibrations of the Al–OH groups. The bands near 1070 and 735 cm$^{-1}$ decrease progressively in intensity by Si addition. However, the three bands at 608, 483 and
molecules are incorporated into a crystal, their six external modes (arising from frustrated rotations and translations) contribute to lattice modes called librations of water molecules (wagging, rocking and twisting modes) and to the acoustic modes. When water is coordinated through oxygen lone pairs to cations (aquo complexes) the metal–oxygen stretching mode and the corresponding deformation modes appear and couple with the other metal–ligand vibrations. The metal–oxygen stretchings are usually located below 600 cm\(^{-1}\). At slightly higher frequencies (900–500 cm\(^{-1}\)) the wagging and twisting modes of coordinated water molecules become internal vibrations of the aquo complex. Coordination per se causes relatively weak perturbations of the stretching and bending modes of water. However, coordination is frequently associated with additional hydrogen-bonding of water, with other water molecules, or with anions present in the crystal structure. This can result in strong downward shifts (to 2000 cm\(^{-1}\)) and broadening of the stretching absorptions, whereas the bending modes are not very sensitive and always fall in the region 1700–1550 cm\(^{-1}\). Asymmetric hydrogen bonding (bonding to only one of the two protons of water) gives rise to spectra where sharp high-frequency peaks occur together with broad low-frequency OH stretching modes.\(^\text{[142]}\)

Spectra of molecular water molecules in crystals and complexes have been collected by Ryskin\(^\text{[130]}\) and by Nakamoto.\(^\text{[8]}\) Protonated forms of water such as the oxonium ion H\(_3\)O\(^+\)\(^\text{[143]}\) have also been investigated.

### 6.6 Oxo Salts

The oxo salts involve oxo anions, which are internally held by covalent bonds between the nonmetal atom (or the metal in a very high oxidation state) and oxygen, giving rise to M–O bond orders ranging between 1 and 2. The oxo anions are further bonded through ionic interactions with the metal cations. The vibrational spectra of oxo salts are therefore dominated, in their high-frequency ranges, by the internal vibrations of the oxo anion. The following sections briefly review the vibrational structure of such anions, in relation to the point group symmetry they can take. Obviously, the splittings of these internal vibrations occur in principle as a result of couplings between the modes of more than one oxo-anionic unit simultaneously present in the smallest Bravais cell.

However, when the unit cell is centrosymmetric the mutual exclusion rule is valid, so that Raman-active modes are IR inactive and vice versa. In practice, for centrosymmetric cells containing \(N\) oxo anions, every internal vibrational mode of the oxo anion gives rise to \(N/2\) IR-active modes and \(N/2\) Raman-active modes.

The cation–anion vibrations (lattice vibrations) are mainly located in the FIR region and their assignments,

6.6.1 Salts with Trigonal-planar and Pyramidal MO$_4^{n-}$ Oxo Anions

The movements of the four atoms present in MO$_4^{n-}$ oxo anions give rise to a total of 12 modes, six of which are associated with the movements of the anion as a whole (rotations and translations, which contribute to the lattice vibrations and to the acoustic modes of the solid). So, six “internal” vibrations occur. The highest symmetry point group for this ion is $D_{3h}$, occurring when it is planar trigonal and isolated. This is typical for isolated carbonate, nitrate and orthoborate anions. In this case, as shown in Table 8, the symmetric stretching gives rise to a nondegenerate Raman-active mode, whereas the asymmetric stretching is doubly degenerate and both IR and Raman active. Two deformation modes occur, the out-of-plane deformation ($\delta$$_{oop}$) which is IR active, and in-plane deformation ($\delta$$_{ip}$) which is degenerate and both IR and Raman active. By lowering the symmetry, e.g. to the $C_{2v}$ point group (as occurs when only two of the three oxygen atoms are equivalent), the doubly-degenerate modes split and all six modes become both IR and Raman active.

The highest symmetry point group for nonplanar pyramidal MO$_4^{n-}$ oxo anions (such as sulfite, selenite, and tellurite anions) is $C_{3v}$. In this case as well, all modes are both IR and Raman active. The symmetric stretching and deformations are nondegenerate whereas the asymmetric modes are doubly degenerate. Such a degeneracy is broken when symmetry is further lowered. Typical positions for the corresponding modes are reported in Table 9.

The commonest crystal structures for AMO$_3$ salts that have been the subject of vibrational studies are calcite (CaCO$_3$, AlBO$_3$, FeBO$_3$, LuBO$_3$, NaNO$_3$),$^{(144)}$ dolomite (CaMg(CO$_3$)$_2$), and aragonite (CaCO$_3$, LaBO$_3$)$^{(145)}$, including aragonite–strontianite solid solutions$^{(146)}$ and nitrates of bivalent metals.$^{(147)}$

6.6.2 Salts with Tetrahedral MO$_4^{n-}$ Oxo Anions

Most of the MO$_4^{n-}$ oxo anions take a tetrahedral-like coordination. In this case there are nine internal vibrations plus six external vibrations contributing to lattice vibrations and to acoustic modes. When the ion takes its highest symmetry ($T_d$ point group) the symmetric stretching and the symmetric deformation are Raman active, the last being doubly degenerate. The asymmetric stretching and deformation are both IR and Raman active and are triply degenerate. By lowering of the symmetry, the degeneracies are broken and all modes can become IR vibrations.

Based on similar considerations to those reported for ionic oxides, are frequently difficult.
and Raman active. This is shown in Table 10, where the typical positions of such modes are also reported for different oxo anions.

Among the different structures of salts containing tetrahedral-like oxo anions AMO₄, scheelite structures (molybdates of Ca, Sr, Ba, Pb, and Cd, tungstates of Ca, Sr, Ba, and Pb) have been the subject of many studies. The structure of α-MnMoO₄ (isostructural with β-MgMoO₄ and β-CoMoO₄) and the structures taken by divalent chromates and sulfates have also been investigated. As for compounds with the formula A₂MoO₄, studies are reported for spinel structures (Na and Ag molybdate, Na tungstate, Ni silicate, and several germanates), olivine and monticellite structures such as Mg₅SiO₄ and some germanates, beryllium silicate structures (Be silicate, Li molybdate and tungstate), and isomorphous alkali chromates and sulfates. Among compounds with the formula A₃(MO₄)₂ studies have been reported on Mg, Ca, Sr and Ba vanadates as well as Ba and Sr orthophosphates, arsenates, chromate and manganate(VI). The IR and Raman spectra of the perrhenate compound Hg₂ReO₅ and of Li₄SiO₄ and Li₄GeO₄ have been reported.

The structure of Mg₃(VO₄)₂ and the coordination of the vanadate ion in this structure are shown in Figure 9. This compound crystallizes in the Cmca = D_{4h} space group with Z = 4. The crystallographic unit cell contains two Bravais cells. Figure 10 shows the IR and Raman spectra. In Table 11 the distribution and assignment of the optical modes are summarized, whereas Table 12 offers a tentative detailed assignment for the V=O stretching mode, showing the effect of decreasing of the symmetry of the anion in the crystal and of coupling of the four units.

The tetrahedral oxo anions can retain one or two protons in the crystal structure, giving rise to monohydrogen or dihydrogen ortho anions. In this case, one or two of the oxygens are certainly unequivalent to the others, and the vibrations of the O–H group also appear. Several studies have appeared concerning metal monohydrogen orthophosphates and dihydrogen orthophosphates.

6.6.3 Salts with Condensed Tetrahedral Oxo Anions

6.6.3.1 Dimeric Condensed Tetrahedral Anions [X₂O₇]ⁿ⁻

Salts where the tetrahedral oxo anions are condensed through common oxygen atoms are denoted by the prefix “pyro” (for dimeric species) or “meta” (for polymeric species). The oxo anions involved have terminal M=O bonds (six in total for dimeric pyro species, two of each atom for polymeric meta anions), and additionally contain M=O–M bridges. Such bridges are generally bent, but they can sometimes be linear, such as for some pyrosilicates, pyrogermanates, pyrophosphates, and pyroarsenates. When the bridge is bent it gives rise to asymmetric stretching, bending/symmetric stretching modes (both are in-plane modes) and an out-of-plane rocking mode (like the Si=O–Si bridges of silica, discussed above). For silicates, the ν_{as} Si=O–Si and ν_{sym} Si=O–SiO occur in the regions 1050–900 cm⁻¹ and near 650 cm⁻¹, respectively. According to Lazarev a linear relationship exists between the bond angle and the parameter Δ = (ν_{as} − ν_{sym})/(ν_{as} + ν_{sym})100. When the bridge is linear (as in thortveitite, Sc₂Si₂O₇), the symmetric stretching could become IR inactive (or very weak if the environment is symmetric). The difference ν_{as} − ν_{sym} is apparently a little higher, with the

* R = Raman.

Several studies have been devoted to compounds containing condensed tetrahedral anions [X₂O₇]ⁿ⁻ (176) such as pyrovanadates, dithromates, pyrosulfates, pyroeselenates, pyrophosphates, pyroarsenates, and pyroniobates. Typical of these compounds are the vibrations of the bridging oxygens. Additionally, the spectra show the vibrations of the terminal MO₃. Each terminal MO₃ moiety gives rise to one symmetric and two asymmetric stretchings, one symmetric and two asymmetric bendings, as well as to one twisting and two rocking modes.

6.6.3.2 Metasilicates, Layer Silicates, and Framework Silicates The vibrational spectra of the different kinds of chain and ring silicates are dominated by the vibrations of the Si–O–Si bridges (as previously discussed for amorphous silicas and for the pyrosilicates) and of Si–O–terminal bonds. Layer silicates (180,181) also present absorptions for Si–O–Si bridges and terminal silanol groups, Si–OH. Both terminal silicate bonds Si–O⁻ M⁺ and silanols give rise to strong IR bands in the region 950–1000 cm⁻¹, which frequently occur also in the Raman spectra. Cyclic structures and particular conformations of the chains can give rise to characteristic features, particularly in the lower frequency regions (Si–O–Si rockings and lattice modes). Terminal silanols, such as those present in the case of layer silicates, also give rise to OH stretching modes strong in IR, such as those of kaolinite (see Figure 8), and these have been characterized by Raman spectrometry. (182) Systematic treatments of the vibrational structures of silicates have been reported. (81,82,173)

Zeolites are microporous framework aluminosilicate materials of great interest in heterogeneous catalysis and
adsorption technology. Some are natural materials, others are synthetic. The electrostatic imbalance arising from the substitution of Al for Si in the silica-like framework is balanced by protons or extraframework cations lying in the cavities. The protonic forms are used as solid acids, whereas the cation-exchanged forms are very useful for selective adsorption. Figure 11 shows the IR and Raman spectra of a typical protonic zeolite, H-ZSM5. This is the Al-containing form of orthorhombic silicalite, discussed above. For this structure there are 323 IR-active modes and 432 Raman-active modes. These spectra show the most typical features of network silica, as discussed above, with few splittings because of the superimposition of many vibrational modes arising from the same vibrations of the basic Si–O–Si units. Figure 12 shows the IR spectrum of the zeolite NaX, a typical cation-containing zeolite whose composition is Na12Al12Si12O48. The structure was first assumed to be cubic with a disordered distribution of Si and Al (Pm3m space group), but it became clear that Si and Al alternate in an orderly fashion. This makes it necessary to multiply the unit cell by eight (Pm3c space group). An enormous number of fundamentals are expected in both IR and Raman spectra. The strong vibrations expected for the zeolite framework are those above 400 cm⁻¹, whereas the bands in the FIR are essentially due to the vibrations of the Na cations in the cavities.[185] IR spectroscopy has been used extensively for zeolite characterization,[110] and Raman spectroscopy is becoming increasing popular.[184]

6.6.3.3 Glasses Raman and IR spectroscopies are unique techniques for the investigation of the structure of glasses. Many studies have been reported concerning silicate-based glasses,[185] in their anhydrous or hydrated states.[186] Both IR and Raman spectra give information on the nature of Si–OH and Si–O–M⁺ terminal bonds with respect to Si–O–Si bridges and of any cyclic structures. The FIR spectra can give information on the coordination state of the cations. Many different compositions have been investigated, such as La aluminosilicates[187] and glasses belonging to the Li₂O–ZrO₂–SiO₂ system.[188] Comparisons between the IR spectra of amorphous and crystalline materials belonging to the MgO–Al₂O₃–SiO₂ and Li₂O–Al₂O₃–SiO₂ systems, including cordierite and ß-eucryptite, have also been reported.[189]

6.6.4 Salts with Condensed Octahedral-like Oxo Anions Chains of oxo anions can condense, giving rise to octahedral-like chains or multiple chains. This is the case for several metavanadates forming double chains [(V₂O₆)₂]ₙ, such as Mg metavanadate. The structure of this compound is shown in Figure 13. In this case vibrational features appear due to triply-bridging O atoms and to pairs of short divanadyl VO₂ bonds.[184] Similarly orthotungstate ions, such as those of metal tungstates in the wolframite structure, condense giving rise to single chains of corner-sharing octahedra (Figure 14). Correspondingly, the spectra can be interpreted in terms

of bridging $W-O-W$ oxygens and of pairs of diwolframyl WO$_2$ terminal groups.$^{(153)}$

6.7 Other Inorganic Materials

6.7.1 Elementary Network Solids

Diamond, silicon, and germanium are elementary solids. They crystallize in the diamond cubic structure, space group $O_h^7$, $Fd3m$, with $Z = 2$. Consequently, only one triply-degenerate mode occurs which is Raman active. No IR-active fundamentals occur. However, overtones or impurity features can be detectable. Moreover, the Raman-active fundamental appears sometimes to gain some IR activity. For diamond, the fundamental Raman mode was determined as early as in 1930 to be at 1332.5 cm$^{-1}$, but tends to shift down to 1320 cm$^{-1}$ in powders of small particle size.$^{(191)}$ Photoacoustic spectra of diamond allow the detection of adsorbed hydrogen and oxygen.$^{(192)}$ In the case of silicon monocrystals the Raman peak is at 520 cm$^{-1}$ and is strongly broadened for amorphous silicon powder. IR spectroscopy is applied to detect and quantify oxygen,$^{(194)}$ hydrogen,$^{(195)}$ and carbon$^{(196)}$ impurities in or on silicon, by measuring the intensities of the Si–O, Si–H, and Si–C IR-active stretching mode. Fundamental TO modes of Ge and cubic Sn fall near 300 cm$^{-1}$ and near 200 cm$^{-1}$, respectively. Raman spectroscopy has also enabled the characterization of tetragonal Ge nanoparticles.$^{(197)}$

Pure elementary carbon can crystallize in the form of graphite. The vibrational structure has been determined by Fateley et al.$^{(3)}$ in terms of the space group $C_{6v}^3$, $P6_3mc$.
with \( Z = 4 \). Due to its conducting behavior, it might not be expected to give either Raman or IR spectra. However, it is reported to give a strong Raman peak at 1580 cm\(^{-1}\) and no IR bands.\(^{598}\) This is consistent with the vibrational analysis performed by Fateley et al.\(^{3}\) assuming that the interaction between the layers is extremely weak and that the vibrational modes of different layers do not couple.

Vibrational and, in particular, Raman spectroscopy have also been successfully applied to glassy carbon,\(^{199}\) diamite and carbon nanotubes,\(^{200,201}\) fullerenes,\(^{202}\) and metal fullerides.\(^{203}\) In all cases the strongest Raman peaks fall in the region 1600–1300 cm\(^{-1}\), characterizing a C–C stretching with a bond order intermediate between 1 and 2.

6.7.2 Binary Semiconductors

Most of group III–V semiconductors (cubic BN, and B, Al, Ga, and In phosphides, arsenides and antimonides) crystallize in the cubic zinc blende (sphalerite) structure \( \text{ZnS (}T_2, F\bar{4}3m\text{)} \) with \( Z = 1 \). This structure is also taken by \( \beta\)-SiC. This is a superstructure of the diamond structure. In this case there is only one triply-degenerate optical mode that is both IR and Raman active. Accordingly, this mode is polar and undergoes LO/TO splitting (see above) so that two peaks occur in the IR and Raman spectra. The position of the TO mode is sensitive to the weight of the atoms involved. It is found at 795 cm\(^{-1}\) for SiC and at 830 cm\(^{-1}\) for BP. For heavier atoms down it appears in the FIR region at 400–100 cm\(^{-1}\).\(^{204,205}\) These materials are therefore useful for windows for the medium IR. The IR reflection spectra allow determination of the composition of semiconducting solid solutions, such as \( \text{Al}_x\text{Ga}_{1-x}\text{As} \) and \( \text{In}_x\text{Ga}_{1-x}\text{As} \).\(^{206}\)

Most group II–VI semiconductors take the hexagonal wurtzite structure, \( \text{C}_6^4, P\bar{6}3m \), as does one of the polymorphs of \( \text{ZnS} \) (wurtzite), \( \text{ZnO, ZnSe, ZnTe, CdS, and CdSe} \). This structure is also taken by the nitrides of Al, Ga, In, and Ti, and by \( \alpha\)-SiC. The vibrational structure is more complex here, with two Raman-active modes (\( E_2 \)), two modes both IR and Raman active (\( A_1, E_1 \)) and one inactive mode (\( B_1 \)) being expected.

6.7.3 Nonoxide Ceramics

Raman and IR spectroscopies are widely used to investigate nonconducting nonoxide ceramic materials. Aluminum nitride takes the wurtzite-type structure. The active modes have been found by Raman spectrometry to lie at 252 (\( E_2 \)), 614 (\( A_1, \text{TO} \)), 660 (\( E_2 \)), 673 (\( E_1, \text{TO} \)), 893 (\( A_1, \text{LO} \)), and 916 cm\(^{-1}\) (\( E_1, \text{LO} \)).\(^{207}\) IR spectroscopy enables distinction between the polymorphs of silicon nitride, namely \( \alpha\)-Si\(_3\)N\(_4\), \( \beta\)-Si\(_3\)N\(_4\),\(^{208}\) and amorphous phases.\(^{209}\)

The materials \( \beta\)-Si\(_3\)N\(_4\) and \( \beta\)-Ge\(_3\)N\(_4\) crystallize in the hexagonal \( \text{C}_{60}^2 \) (\( P\bar{6}3/m \)) space group with \( Z = 2 \); their IR spectra show that Si–N–Si asymmetric stretchings fall in the region 1100–900 cm\(^{-1}\), whereas Ge–N–Ge asymmetric stretchings fall in the region 920–800 cm\(^{-1}\).\(^{210}\) The substitutional solid solutions of Al and oxygen into \( \beta\)-Si\(_3\)N\(_4\) give rise to “\( \beta\)’-sialons” (Si-Al oxynitrides). This substitution gives rise to broadening and shifts of the
IR absorption bands, allowing the determination of their composition. The vibrational spectra of silicon oxynitride Si$_2$ON$_2$, where an oxygen bridge forms between SiN$_3$ units, has been the subject of skeletal vibrational studies and lattice dynamics calculations. Boron nitride takes the zinc-blende diamond-like structure with tetrahedrally coordinated B and N atoms or, alternatively, a hexagonal graphite-like structure (h-BN, $D_{6h}^1$ space group). In this case both types of atoms have trigonal coordination. Two B–N stretching modes are detectable, one IR active and the other Raman active (1366 and 1373 cm$^{-1}$, respectively), characterizing the vibrations of BN$_3$ planar units. A turbostratic sample shows vibrational features close to those of h-BN. The wurtzite structure is adopted by α-SiC, and other polymorphs present highest frequency fundamentals in similar frequency ranges. IR spectra enable the detection of hydrogen and oxygen impurities in these materials.

The vibrational spectra of boron carbide B$_{13}$C$_2$ have also been investigated.

6.7.4 Halides and Sulfides

The halides of most alkali metals take the rock-salt structure, which is Raman silent with only one triply-degenerate IR-active mode (see Table 1). The maximum of the transverse mode is located below 400 cm$^{-1}$ in all cases and shifts to lower frequencies on increasing the weight of either anion or cation. The CsCl structure taken by Cs and Tl$^I$ halides (space group $Pm3m = O_h^1$ space group) also gives rise to only one triply-degenerate IR mode which is located (according to the relevant weight of the cations involved) in the FIR. This makes
both NaCl-type and CsCl-type halides useful materials for windows for the medium IR region. Several halides of divalent metals take the rutile structure (some slightly distorted), or the CdF₂ structure which is strongly related to the brucite structure of MgCl₂. Fluorite CaF₂ (Fm3m = O₅₆ space group, Z = 4) is largely used as a window material for IR due to its nonsolubility in water. The halides of Ba and Pb(crystalize in the Pbmn = D₂h space group with Z = 4. Their IR spectra are quite complex. However, alkaline earth halides absorb IR at higher frequencies than for the corresponding alkali metal halides (the highest frequency IR absorption maximum is at 410 cm⁻¹ for CaF₂ and at 465 cm⁻¹ for rutile-type MgF₂).

Sulfur is heavier than oxygen, hence vibrational modes involving metal–sulfur bonds fall at lower frequencies than for the corresponding metal–oxygen bonds. Bivalent metal chalcogenides constitute the II–VI class of semiconductors, taking either the zinc-blende or the wurtzite structures (see above). The position of the fundamental modes of zinc chalcogenides decreases by increasing the chalcogen weight. The fundamental modes of Ca, Sr, and Ba sulfides fall in the FIR region (below 400 cm⁻¹). Rare earth sesquisulfides have been the object of recent Raman investigations. The sulfides of tetravalent Mo and W have a well-known layered structure, but they can also be prepared in fullerene-like and nanotube-like forms. These MoS₂ and WS₂ polymorphic forms have been characterized by Raman spectroscopy. The spectra of several sulfide and chalcogenide structures have been reported and discussed.

### 6.8 Unusual Applications

The application of vibrational spectroscopies to different fields of inorganic materials research is expanding. Among the many interesting and unusual applications are Raman spectroscopic sensors for in situ mineral characterization on planetary surfaces, the study of decorated stained glass to characterize historic pigments such as those used in native American Indian rock art and by Romans and determination of the composition of medieval pottery fragments from the south of Italy.

Vibrational techniques are used in the characterization of minerals and hydrated products of construction cement, ferroelectric and ferroelastic materials, nonlinear optical materials in petrography and the analysis of soils. Raman techniques have been applied in ceramics science for the analysis of polymorphs of silicate materials and their thermal expansion properties. FIR is used to characterize dielectric ceramics for microwave applications. Vibrational spectroscopies are used to characterize solid catalysts and to investigate inorganic materials of biological and medical interest, such as urinary stones and hydroxyapatite.

This introduction opens by discussing the distinction between kinetic and thermodynamic determinations. After defining equilibrium, pseudo-equilibrium, and dynamic measurements, a historical perspective is given that covers early tests and publications to the present overall scope of kinetic determinations. In closing, a listing of selected bibliography is presented; this follows a short narrative emphasizing that kinetics goes beyond determinations in analytical chemistry.

1 EQUILIBRIUM AND KINETIC DETERMINATIONS

The two pillars of the physical sciences are their kinetic and equilibrium components.

1.1 Comparison of Thermodynamic and Dynamic Measurements

All physical and chemical processes, once triggered, evolve to equilibrium by a pre-equilibrium evolution defined as the kinetics of the processes. Practically, however, nothing in this world is perfectly static. Physical and chemical processes do not abide; they occur. Physics and chemistry are scientific disciplines focused on changes that take place in time. Changes occur even in systems considered to be at equilibrium. For all practical purposes, however, the chemical composition of a system and its physical properties remain constant once the system has reached equilibrium, but both change with time during the dynamic evolution to equilibrium.

The rate of transient physical processes as well as the rate of chemical changes can both be used for quantitative analytical purposes. Kinetic determinations based on fluorescence or phosphorescence, for instance, involve primarily physical processes. The bulk of analytical applications based on measurements during transient processes, however, exploit chemical changes. Consequently, this section of this Encyclopedia focuses, primarily, on chemical kinetics without neglecting physical processes. Experimentally, measurements of the system composition are possible while reaching equilibrium (kinetic measurements) or with the system at equilibrium (thermodynamic measurements). Consequently, the contemporary analytical chemist can choose to make measurements (e.g. determination of the concentration of a particular analyte) during evolution to equilibrium or at equilibrium. Essentially, kinetic determinations are based on measurements while the composition of the system is changing with time and without disturbing the kinetic process. It is possible, however, to freeze the composition of the system at any given time during the evolution to equilibrium (quenching a given reaction), and to make the ‘thermodynamic measurement’ at this ‘forced equilibrium’ situation. Then, relate the composition to the known kinetic behavior of the analyte to arrive at its original concentration in the sample. This practice is seldom used today, but was quite common some years ago, and although technically the measurement is a thermodynamic one, the methodology is classified as resulting in a kinetic determination.
The simple formulation, Equation (1):

\[
\text{Reactants} \xrightarrow{\text{Products}}
\]

and the corresponding kinetic symbolism, (Equation 2), in which \( t = \text{time} \):

\[
\frac{dC_{\text{products}}}{dt} = -\frac{dC_{\text{reactants}}}{dt} = \text{rate of reaction}
\]

allows the time regions which define kinetic and thermodynamic measurements to be visualized. This is shown in Figure 1.

The rate profile shown in Figure 1 is exhibited by all chemical reactions and physical processes regardless of their complexity. Although the didactic value of this figure is obvious for illustration of the two measurement approaches available for analytical determinations, direct measurement of reaction rates is not practical. What the chemist usually measures directly is some electrical signal, \( S \), related to concentration. In some cases (e.g. conductance or amperometric measurements), \( S \) is linearly related to concentration (Equation 3):

\[
S = \$C_R
\]

where \( \$ \) is the proportionality constant or transfer function in electrical units per concentration units and \( C_R \) represents the concentration of a given reactant at a given time. In some instances, \( S \) is not a linear function of \( C_R \) (e.g. optical absorption or potentiometric measurements), and the direct instrument response can be written as Equation (4):

\[
S = fC_R
\]

where \( f \) is an arbitrary function. The mathematics is more complicated, generally resulting in nonlinear calibrations.

In any event, \( C_R \) can always be obtained from \( S \). With a knowledge of concentration and its change with time, reaction rates can then be calculated. Physical changes in the kinetic region are also followed by the change of an electrical signal from which rate information is extracted.

### 1.2 Approaches to Dynamic Measurement of Concentration

Table 1 summarizes the most important approaches for kinetic determinations based on concentration estimates obtained while the system is evolving to the equilibrium position. An understanding of the operational characteristics of kinetic-based determinations requires a background in the mathematical formulation and manipulation of rate expressions. Most of this background is addressed in detail in several of the articles within this section. In general, however, such a background can be kept simple considering that chemical reactions employed in virtually all kinetic determinations are bimolecular. The analyte species, \( A \), is one of the reactants, and the other reactant, \( R \), is present in large excess rendering pseudo first-order conditions under which:

\[
C_R \text{ at any time } t = C_A \text{ initial } e^{-kt}
\]
remain virtually unchanged, the reversed process can be ignored because \( C_{\text{PRODUCT}} \approx 0 \), and a pseudo-zero-order process is in operation such as Equation (6):

\[
- \left( \frac{dC_A}{dt} \text{ at any time } t \right) \approx k \cdot C_{A, \text{initial}} \cdot C_{R, \text{initial}}
\]

\[
\approx \text{initial rate} \approx \text{constant} \quad (6)
\]

Equation (6) provides the basis of a very common approach to dynamic measurement of concentration, the initial rate method, since if the initial rate is plotted against \( C_{A, \text{initial}} \) should yield a straight line useful as a calibration plot for the determination of \( C_{A, \text{initial}} \). Three approaches are used to extract initial rate information, they are:

1. the derivative or slope approach, in which electronic differentiation provides \( dS/dt \);
2. the fixed time or constant time approach;
3. the variable time approach.

The fixed time and variable time approaches result from the use of the integral forms of the rate equation, but under conditions such that Equation (6) is approximately valid. The fixed time method involves measurement of a small signal change, \( \Delta S \), at a finite but short \( \Delta t \) close to \( t = 0 \). In the variable time approach, \( \Delta t \) is measured for a finite but small \( \Delta C_R \) or \( \Delta C_A \) close to \( C_{R, \text{initial}} \) or \( C_{A, \text{initial}} \). In both cases, the ratio \( \Delta S/\Delta t \) gives an approximate estimate of the initial rate.

Initial rate measurements are often recommended because the back reaction does not contribute appreciably to the overall rate, and complications from side reactions are less possible at the beginning of any reaction.

To determine the initial concentration of a desired species, monitoring of the concentration of at least one of the reactants (or products) as a function of time is needed. Continuous measurement of the change in chemical composition is possible by physical, but not by chemical methods, and the observable rates are limited only by the response time of the instruments. With well behaved kinetics and the concentration–time profile obtained by continuous monitoring, two other approaches based on dynamic measurement of concentration can be identified:

1. the derivative approach, and
2. methods based on kinetic plots such as the method of the tangents.

The derivative approach considers that at any time \( t \) the value of \( dS/dt \) is indicative of the instantaneous rate. If most of the concentration–rate profile is available, relaying on a single derivative (single point measurement) is unwise. This is particularly true now that we enjoy the brute force of the digital computer. The computer makes multipoint-based measurements possible, and this offers two main advantages:

1. less experimental work is needed to seek discriminative variables, and
2. the use of a large number of data points reduces errors.

Which approach is used, of those listed in Table 1, primarily depends on available instrumental and/or computational capabilities, and on the type of kinetic method being applied. Table 2 summarizes the main types of methods used in kinetic-based determinations. Except for special cases, all these methods use the measurement approaches listed in Table 1. The measured signal, proportional to concentration, is in all these cases used to derive rate information. The converse approach of estimating the equilibrium concentration (signal) from signals measured under dynamic conditions is less often used. This approach characterizes the so-called predictive methods. Predictive methods are of relatively recent application for kinetic-based determination, but their foundation can be traced back to considerations advanced in 1926 by Christie Smith.

Some approaches to mixing (e.g. centrifugal mixing or continuous-flow mixing) also provide unique means for measurements under dynamic conditions. Unsegmented continuous-flow mixing of the type encountered in the approach commonly known as ‘flow injection analysis’ provides, in its simplest and most commonly used form, fixed-time measurements under dynamic conditions. Programmed continuous-stopped-continuous-flow procedures in unsegmented systems provide another avenue for signal measurement under dynamic conditions of utility for kinetic-based determinations.

1.3 Equilibrium and Pseudo-equilibrium Measurements to Support Kinetic-based Determinations

The progress to equilibrium of any process can be terminated by quenching the reaction. Quenching is possible by several means, including rapid cooling, precipitation of one reactant, addition of free radical scavengers, or addition of a complexing agent or other chemical species that renders inactive one of the reactants. Quenching by adding an acid or a base can be used, for example, to stop most enzyme-catalyzed reactions. Since the progress to equilibrium has been interrupted, for all practical purposes Equation (7) is valid:

\[-\frac{dC_{\text{REACTANTS}}}{dt} = \frac{dC_{\text{PRODUCTS}}}{dt} = 0\]  

and the system, composition-wise, is at ‘equilibrium’, and therefore the measurement of \( S \) is not performed under dynamic conditions. The corresponding values of \( S \), however, can be used to calculate concentrations at given times and apply, for example, the fixed-time or variable-time approach to effect a kinetic-based determination. In such cases one of the times or one of the concentration values may be equal to zero. The speed of today’s signal detection/manipulation devices has practically made obsolete quenching for kinetic-based determinations, but quenching is always an approach available to the analytical chemist.

A unique steady-state situation (pseudo-equilibrium condition) is imposed on a system by stat procedures.\(^6\) These procedures are an example of kinetic-based determinations in which a solution containing a chemical species capable of counteracting a chemical change in the system is added to the system. If the rate of delivery matches the rate of change in the system, a steady state situation is approached (stat condition) in which \( dS/dt = 0 \). The rate for restoring the value of \( S \) serves to deduce quantitative information for determinative purposes. This approach has its origins in the determination of enzyme activity with the maintenance of \( pH \) at about a constant value (generally the optimum \( pH \) for the enzyme) by a \( pH \)-stat procedure, but its report in the literature for other type of kinetic-based determinations is scarce.

2 HISTORICAL PERSPECTIVE

Difficult as it is to establish historical priorities, events that left a historical mark – e.g. journal papers and books – can be recognized.

Historically, equilibrium-based determinations predated kinetic-based ones, and they dominated the arena of chemical analysis for a long period of time. During this dominance, kinetics was considered mainly in the context of undesirable effects (e.g. the sluggishness of attainment of some end-points in redox titrimetry). In chemical analysis, the presence of kinetic concepts was very limited in those years, although an outstanding example of positive consideration was present in the recognition that the rate of crystal growth greatly influences the filterability and purity of a precipitate. Precipitation from homogeneous solution,\(^7\) an ingenious application of chemical kinetics, seems to date back to 1858 with the work of Chancel\(^8\) on the separation of iron and aluminum employing thioulsulfate.

Difficult as it is to establish historical priorities, a few examples can be cited and are included in the following section.

2.1 Early Tests and Publications

Nonenzymatic catalysis seems to provide the first recorded analytical development of a kinetic-based method. As early as 1876, Guyard (who was also known by the alias Hugo Hamm) discussed the catalytic effect of vanadium on the perchlorate ion oxidation of aniline to yield aniline black and proposed the use of this reaction to detect the presence of vanadium.\(^9\) A decade later, Osmond\(^10\) described a semiquantitative estimation of vanadium by considering that the amount of aniline black formed after a given, fixed, time is proportional to the amount of vanadium present in the sample. The paper was written by Osmond after Georges Witz’ death, but was inspired by Witz’ studies on certain chemical modifications of cotton, and Witz is listed as coauthor. Oxycellulose threads were dipped into vanadium-containing solutions and subsequently into an aniline-chlorate mixture for a fixed time. The practical minimum detectable quantity can be estimated as 0.000005 mg of vanadium, but the volume of sample used, unfortunately, is not indicated in the publication. This paper is one of the first to report a nonenzymatic quantitative estimation based on a catalytic procedure, and using a fixed time procedure. Osmond also indicates in the same publication that the method was used to recognize the presence or absence of vanadium in samples of different natural mineral waters. In 1881, a few years earlier than the publication of the paper with Witz and Osmond authorship, William Roberts\(^11\) published what can be considered the first application of the variable-time procedure. Roberts was a physician in the Manchester Royal Infirmary and a professor of clinical medicine at Owens College. The procedure proposed by Roberts was inspired by the work of Brown and Heron\(^12\) on the transformation of starch by malt infusions, and the work of Johan Gustaf Kjeldahl on the measurement
of the comparative activity of malt infusions and of saliva at the Carlsberg Institute for research on brewing and the beer industry. Contributions from clinical medicine and industrial enzymology have undoubtedly left an indelible mark in the early history of kinetic-based determinations. Almost half a century passed until catalytic-based determinations were cited again in the records of chemical literature. This time Sandell and Kolthoff\(^\text{13}\) introduced the determination of iodide based on its catalytic action on the cerium(IV) oxidation of arsenic(III) by a variable-time procedure. Almost simultaneously, in Hungary, Szebbellédy and Ajtai\(^\text{14}\) reported a catalytic-based determination of as little as 0.6 ng of vanadium. A large number of determinations based on catalysis have been described since then and many found a place in the first monograph on kinetic methods of determination authored by Yatsimirskii and published in 1966\(^\text{15}\) (see Figure 2). A monograph by Arkosi\(^\text{16}\) on ‘catalytic analysis’ preceded by about 10 years the book by Yatsimirskii. Yatsimirskii’s book, however, appeared at a time when instrumentation was making measurements under dynamic conditions competitive, and consequently had a significant impact on the development of the topic.

As early as 1921, Clarens\(^\text{17}\) applied the laws of chemical kinetics to the dissolved oxygen oxidation of tannins and proposed a fractional determination of tannins in general and in wines in particular. Clarens paper seems to be one of the earliest uses of differential rates for the in situ determination of more than one species in solution. It also points to a pioneering of a kinetic-based approach utilizing uncatalyzed reaction rates. In contrast with catalytic methods, simultaneous determination of more than one chemical species (differential rate methods) are not necessarily aimed at determining low concentrations and most of the reactions employed are uncatalyzed. Relatively more recently, a paper by

---

**Figure 2** Front and reverse of the title page of Yatsimirskii’s book ‘Kinetic Methods of Analysis’.
Kolthoff and Lee\(^{18}\) demonstrated that kinetics, via
differential reaction rate methods, can give access to
medium and major components in a mixture, and thus
complementing the accessibility to very low concen-
trations afforded by catalytic methods. Although the
procedure introduced by Kolthoff and Lee, known today
as the single-point method, has found infrequent use, it
initiated a period extended through the 1950s and 1960s
in which differential rate methods drew attention, mainly
for the determination of organic species. Lee’s chapter in
the series ‘Organic Analysis’\(^{19}\) and the book by Fritz and
Hammond\(^{20}\) on quantitative organic analysis emphasize
the impact of simultaneous determination of more than
one organic chemical in a mixture exploiting rate differ-
ences. The chapter by Lee\(^{19}\) offered the interesting
forecast that enzymes would find a place in analyti-
ical chemistry as purity of preparations and commercial
availability would make them attractive in kinetic-based
methodology. Time has proved Lee’s forecast as true.

\(\text{2.2 From Timers and Watches to Semi-automated}
\text{and Automated Reaction Rate Methodology}\)

Mixing and timing have been the two experimental oper-
ations critical for the development of kinetic methods.
Manual mixing (Figure 3) and watches provided the
earliest means for implementing such experimental oper-
atations, and their crude performance did little to favor the
use of kinetics in analytical determinations.

Resistance to accept kinetic-based determinations
persisted throughout the 1950s; the main arguments
being that time was an elusive variable to measure
and/or that concentration was difficult to ascertain at
given times if the system was evolving to equilibrium.
The 1960s, however, brought accessibility to electronic
devices, particularly the use of operational amplifiers,
that demonstrated as possible the accurate and precise
measurement of signals during evolution to equilibrium:
both time and concentration could be reliably known
simultaneously. The road to automation of reaction-
rate methodology was opened in the 1960s (see Mottola,
Kinetic Aspects of Analytical Chemistry, 8–11) and worth
mentioning for their pioneering nature are the papers by
Malmstadt and Hicks\(^{23}\) and Blaedel and Hicks.\(^{24}\)
Undoubtedly, the use of strip-chart recorders played
an important role in the late 1950s and early 1960s,
allowing the recording of signal change with time in
relatively slow chemical changes. Figure 4, taken from
Yatsimirskii’s book illustrates the use of such read-out
devices.

Malmstadt and Hicks\(^{23}\) reported on how to assemble,
from commercially available units and interface it with
a controller, an instrument that greatly facilitated the
rate-based enzymatic determination of glucose in clinical
samples. Blaedel and Hicks\(^{24}\) introduced the first
unsegmented continuous-flow sample/reagent(s) processing
system for the continuous measurement of the rate of
an enzyme-catalyzed reaction.

The logical next historical development in kinetic-
based determinations was a spin-off from electronics:
the exploitation of computers for feedback/feedforward
control of instrumentation, signal collection and manipu-
lation, and data treatment (e.g. application of multipoint
KINETIC DETERMINATIONS

2.3 From Determination of Inorganic Species to the Determination of Organic and Biochemicals

The developments in the field of kinetic-based determinations have paralleled the evolution experienced by chemical analysis throughout the years. During the years in which thermodynamic-based measurements dominated the analytical subdiscipline of chemistry, the attention was focused on what can be called 'mineral analysis'. In those years then, the focus was on the determination of inorganic species. Catalytic determinations, which opened the road to measurements under dynamic conditions, did not escape such an influence, and most of the early catalytic determinations were of inorganic species. Therefore, it is not surprising to find a few catalytic determinations cited as part of 'inorganic microchemistry' in some early reviews. More than half of the citations in these reviews, however, reported the use of organic reagents for equilibrium-based measurements aimed at the determination of inorganic species, a 'hot' topic at the time. In the middle to late 1940s, the need for training inorganic chemistry for analytical chemists became more widely recognized. This is perhaps best summarized in the following words lifted from the Preface of a timely book on functional analysis by Siggia:

I recognize the great need which exists in our colleges and universities for formal training in the field of quantitative organic analysis, and I know that very few schools offer this training. Here chemists are needed who are trained to do analytical work with compounds of this type. It is my belief that quantitative organic analysis should be included in the regular analytical courses that are usually entirely inorganic.

These were the times when elemental analysis data was beginning to be supplemented with information extracted from functional group analysis based on acid–base and redox titrimetry as well as on the measurement of gases consumed or liberated by reactions of analyte and reagents. In parallel, instrumental techniques such as chromatography, electrophoresis, polarimetry, light absorption, and polarography – to name a few making an impact at that time – were helping to blur the inorganic prevalence. Kinetic-based analytical methods backed the trend in the 1950s and 1960s which can be considered to be triggered by Kolthoff and Lee’s paper introducing the single point method. Statements such as those by Fritz and Hammond in their book on quantitative organic analysis (page 167):

It is the opinion of the authors that the analyses described in which the differential kinetic procedure was used could not have been solved by any other method of comparable simplicity.

as well as that of Lee forecasting the impact of enzymes on analytical chemistry, accurately framed the position of kinetic-based determinations paralleling the evolution of analytical chemistry itself (page 242):

There is no doubt that methods based on catalysis by enzymes will increase in number and practicability as advances are made in the study of these substances and as more enzymes of known activity and purity become commercially available.

Transition from inorganic to organic and to biochemical analysis was paved at that time and kinetic-based measurements played an important role in such transition.
3 KINETICS IN ANALYTICAL CHEMISTRY: BEYOND DETERMINATIONS

Many analytical techniques or approaches, if scrutinized closely, are perceived to be of kinetic nature or to involve key kinetic components.

Chemical reactions in solution provided the early foundation and constitute an important portion of the subdiscipline we know today as analytical chemistry. Equally important, however, is the realization that many analytical methods and techniques are solely based on the measurement of a physical property of the system or chemical species of interest. In either case – whether a reaction-based or a physically-based measurement – measurements under dynamic conditions can not only generate information useful for determination of chemical species, but also for the fundamental understanding of the process(es) involved. In the realm of analytical chemistry, the relevance of kinetics goes beyond determinations.

3.1 Chemical Reactions and Physical Processes in Analytical Chemistry

The bulk of analytical chemistry based on chemical reactions focus on solution chemistry, particularly with water as solvent. Traditionally, four basic types of reactions have been used, and they still continue to be used, in both equilibrium-based and kinetic-based methods. They are:

1. precipitation (ion-exchange reactions),
2. acid–base (proton-exchange reactions),
3. redox (electron-exchange reactions), and
4. complexation (ligand-exchange reactions).

In kinetic-based methods, proton transfer and precipitation reactions have had very limited use. On the other hand, redox reactions dominated applications based on nonenzymatic catalytic determinations, and ligand exchange reactions have been frequently used in the development of differential rate methods.

Although not as easily recognized, rates of change of physical properties of a system play important roles in contemporary analytical chemistry. The rate of mass transfer is a case at hand. Diffusion and convection as time-dependent processes, for example, are particularly critical in electroanalytical chemistry, separations, and continuous-flow procedures. In the field of spectroscopy, excitation–absorption–emission are all rate driven processes critical in atomic as well as molecular spectroscopy.

3.2 Some Areas of Analytical Chemistry in which Kinetics Play a Direct or Indirect Role

Although the theme of this Encyclopedia is focused on determinations and instrumentation, a few words about other roles of kinetics in analytical chemistry are in order. Practically, in all areas of interest to analytical chemistry, kinetics play an important direct or indirect role. This is because time-dependent chemical and physical processes are ingrown into most aspects of analytical chemistry. This is true from very classical methodologies (e.g. gravimetric analysis) to rather recent tools (e.g. glow discharge optical emission spectroscopy and cavity ring-down laser absorption spectroscopy). The theoretical aspects of precipitation are derived from theories on nucleation and crystal growth. Kinetics is of interest in many separation approaches such as solvent extraction (for example in metal ion separation), ion exchange, and chromatography in general. Both the rate of electron transfer at the electrode/solution interface and chemical kinetics in and in the vicinity of the double layer are of paramount importance in electroanalytical chemistry.

Direct injection enthalpimetry is one of the thermal methods in which kinetics is most obvious since it is based on monitoring the change in temperature with time. Other thermal methods reveal kinetic in their theoretical foundations such as it is the case in differential thermal analysis. Continuous-flow sample/reagent(s) processing for the so-called ‘wet chemistry’ are all approaches plentiful in kinetics.

The enumeration of analytical approaches rich in kinetics becomes almost endless, including for example typical spectroscopic (e.g. nuclear magnetic resonance) and non-spectroscopic methods (e.g. mass spectrometry), but before calling to a close this section a mentioning of some well established spectroscopic approaches (e.g. absorbance-based measurements and luminescence-based methods) as well as some not so popularized as yet (e.g. glow discharge emission and cavity ring-down absorptiometric measurements) is pertinent. The kinetic nature of fluorescence and phosphorescence is well established, and even one of the distinctive aspects that distinguish phosphorescence from fluorescence is rate related, i.e. the decay periods are much longer in phosphorescence because relaxation from the triplet to the ground state singlet is forbidden by spin symmetry.

Bioluminescence is a special case of chemiluminescence in which the chemical reaction responsible for photon emission occurs or can occur in nature. Both, however, are observed when an electronically excited product is produced that either luminesces or transfers its excess energy to another molecule that then luminesces. Kinetically, such situations result in series processes
leading to transient signals and which can be symbolized as Equations (8–11):

\[
\begin{align*}
A + B & \longrightarrow C^* \\
C^* & \longrightarrow C + \text{hv} \\
C^* + D & \longrightarrow D^* + C \\
D^* & \longrightarrow D + \text{hv} \quad \text{or} \quad D^* + \text{hv}
\end{align*}
\]

(8–11)

A free energy change of at least 44 kcal mol\(^{-1}\) is required for emission of light in the visible region of the spectrum. This is usually provided by redox reactions involving oxidants such as \(\text{O}_2\) and \(\text{H}_2\text{O}_2\) and cyclic hydrazides (e.g. luminol or acidrine derivatives). Temporal resolution of events in the picosecond and even femtosecond range is of interest in analytical detection, particularly in time-resolved spectroscopic measurements.

Kinetics is not only prominent in well established spectroscopic techniques. Rather recent additions to the spectroscopic tool chest are successful because of critical kinetic components, or because the measurement approach itself is kinetic in nature. In glow discharge optical emission spectroscopy, for example, signals are directly related to the supply rate of element into the plasma. In the so-called cavity ring-down spectroscopy, the measurement of photon absorption is based on a time measurement: the time for the detected photomultiplier response (signal) to decay to \(1/e\) of its original value.

Although a catalyst does not shift the position of equilibrium but it does markedly change the reaction rate, because the catalyst lowers the activation energy of a reaction providing an alternative favorable route for the formation of the products. The reacted catalyst is regenerated and is repeatedly involved in an indicator reaction. When the rate depends on the concentration of the catalyst, it can be determined by measuring the change in the physical properties of the reactants and/or products in the indicator reaction. The change in a physical property such as absorbance, fluorescence, chemiluminescence (CL) or electrode potential of a reaction system is usually monitored with time. This methodology is called catalytic methods or kinetic–catalytic methods of analysis.

Kinetic–catalytic methods of analysis based on catalyzed reactions have progressed recently and have been applied to trace analyses for various catalysts (element) because of their extremely high sensitivity, low limit of detection and selectivity. Several reactions such as redox, ligand substitution and complexation reactions have been utilized as indicator reactions for the development of kinetic–catalytic methods of trace analyses. Most of the catalysts in redox reactions are metal ions or inorganic anions having different oxidation states such as cobalt, copper, chromium, iron, manganese, vanadium, selenium, iodide, bromide and nitrite. Oxidants capable of regenerating the catalyst are hydrogen peroxide, chlorate, bromate, periodate and dissolved oxygen. Reductants include ascorbic acid, hydroxylamine, hypophosphorous acid, alkali sulfides, dithiothreitol and tin(II).

Certain substances significantly increase the rate of catalyzed reactions. These substances are referred to as activators and have been defined as substances that do not catalyze the indicator reaction but enhance the catalytic effect of the catalyst. Activators provide high sensitivity and selectivity in kinetic–catalytic methods. Such improved specificity can be expected to eliminate the preliminary separation in many instances.

As the measurement includes time as an experimental variable, care is needed to ensure that mixing of reagents takes place at regular time intervals to obtain highly accurate results using a manual procedure. Such disadvantages in the manual system can be overcome by using flow-injection analysis (FIA), in which the reaction time can easily be controlled by varying the flow rate of the solutions and the length of the reaction coil.

Kinetic–catalytic methods allow the determination of various elements at nanogram and picogram levels ($10^{-11}$ M) with a simple and reasonable equipment. The detection limits (DLs) of the methods are of the order of picograms per milliliter with good accuracy and precision and are almost equal to those for inductively coupled plasma mass spectrometry (ICPMS).

The application of catalytic effects of metal ions in titrimetry has been recognized for a long time. This methodology is called catalytic titration and involves two
consecutive reactions, i.e. titration reaction and indicator reaction. The determinable concentration is almost $10^{-6}$ M of the metal ions.

1 INTRODUCTION

Methods of chemical analysis for the analyte in a mixture are mainly classified into two classes, thermodynamic (or static) and kinetic (or dynamic) classes, according to the nature of measurement employed. A thermodynamic method generally involves changing the equilibrium conditions of the reaction system to proceed essentially to completion, that is, the equilibrium greatly favors the reaction products, and a physical property of the solution, corresponding to the concentration of either the reactants or the products, is measured by using conventional analytical methods such as spectrophotometry, fluorometry, chemiluminescent method, atomic absorption spectrometry, flame spectrometry, an electrochemical method, and so on. A kinetic method involves the measurement of the rate of the chemical reaction under nonequilibrium conditions as a function of time. Furthermore, kinetic methods of analysis are classified into two categories, catalytic and noncatalytic determinations. These methods have been subdivided according to the type of reaction and to the procedure employed for determining single or multiple components in a mixture. Classification of kinetic methods is listed in Table 1.

The change in a physical property such as absorbance, fluorescence, CL, electrode potential of a system is usually monitored. Numerous batch and flow-injection methods have been reported for the catalytic determination of trace elements. Kinetic–catalytic methods are usually much more sensitive than thermodynamic ones based on stoichiometric reactions. The sensitivity of the kinetic–catalytic methods of analysis is estimated to be $10^{-16}$ M or $10^{-5}$ pg mL$^{-1}$, under the most suitable conditions, when a spectrophotometric method is used for determining reaction rate. The use of activators in the kinetic–catalytic methods increases further the sensitivity and selectivity of the methods. Improved specificity can be expected to eliminate the preliminary separation in many instances. The details of the action of activators will be discussed in section 4.

A catalytic reaction was first applied to quantitative analysis by Guyard who reported a catalytic determination of vanadium based on its catalytic effect on the oxidation of aniline by chlorate in 1876. Nearly 60 years later, Sandell and Kolthoff reported the iodide determination using its catalysis on the reaction of As(III) with Ce(IV). Equation (1)

$$\text{As(III)} + 2\text{Ce(IV)} \rightarrow \text{As(V)} + 2\text{Ce(III)} \quad (1)$$

This method is probably the only catalytic method for iodine as iodide that has been extensively used. After that, kinetic–catalytic methods have been recognized as offering a valuable approach to trace analysis, because of their high sensitivity, low limit of detection and good selectivity, and have been the subject of reviews and monographs. Since 1964, biennial reviews entitled “Kinetic Determinations and Some Kinetic Aspects of Analytical Chemistry” have been published in Analytical Chemistry. The contents of the reviews consist of kinetic methods for determination of catalyst, kinetic methods based on activation or inhibition of catalysis, titrimetric methods with catalytic end-point indication, kinetics and mechanisms of some catalyzed reactions of analytical interest, applications of luminescence, kinetic methods based on uncatalyzed reactions, differential methods (simultaneous multicomponent determinations), instrumentation, and so on. According to Mottola, the idea of an international gathering of chemists interested in all kinetic aspects of analytical chemistry was conceived in the late 1970s. Since the First International Symposium on Kinetics in Analytical Chemistry took place in Cordoba, Spain, 1983, a series of symposia has been held every three years. The details of many of the contributions presented at these meetings from the second symposium can be found in The Analyst.

This article focuses on kinetic–catalytic methods for nonenzymatic reactions in homogeneous systems.

2 THEORETICAL BASES OF KINETIC–CATALYTIC METHODS OF ANALYSIS

A catalyst is a substance that alters the rate of a reaction without being consumed or shifting the position of equilibrium of a reaction system. The catalyst lowers the activation energy of a reaction, providing an alternative favorable route for the formation of the products. Reacted
catalyst is regenerated and repeatedly involved in the reaction, although the catalyst is chemically unchanged at the end of the reaction. The rate of catalyzed reaction is proportional to the concentration of the catalyst under given conditions and can therefore be employed for the catalyst determination by using a suitable procedure.

In the kinetic–catalytic methods, the main reaction in which the species participate is called the indicator reaction. This reaction is always thermodynamically favored to completion, but is kinetically unfavorable. One type of indicator reaction frequently used in the kinetic–catalytic methods is a redox reaction in which the catalyst M, usually a multivalent ion, changes its oxidation state during the reaction as follows, Equations (2–4):

\[ S + R \rightarrow P + Q \quad (2) \]
\[ S + M \rightarrow P + M' \quad (3) \]
\[ M' + R \rightarrow Q + M \quad (4) \]

where S and R are the substrate and reagent, respectively, and P and Q are the reaction products in the indicator reaction, Equation (2). The indicator reaction is usually very slow. However, when an ion M acts as a catalyst, it accelerates the formation of the product P and is then converted into a different oxidation state, M' by reaction shown in Equation (3). If M' is regenerated again to M by reaction shown in Equation (4), the formation of P is catalyzed by a trace amount of M. Thus small amounts of M even at subnanogram levels can be determined by measuring the rate of the formation of P. It is also true from Equation (4) that M' can be determined as well as M.

The rate of reaction (2) catalyzed by M, v, is expressed as Equation (5):

\[ v = k_u[S][R] + k_c[S][R][M] \quad (5) \]

where \( k_u \) and \( k_c \) are the rate constants of uncatalyzed and catalyzed reactions, respectively, and \( a, b \) and \( c \) are reaction orders with respect to each species. In most cases, the reaction is first-order in S and R, and also in M. Then rate Equation (5) can be written as:

\[ \frac{d[S]}{dt} = \frac{d[P]}{dt} = k_u[S][R] + k_c[S][R][M] \quad (6) \]

The concentration of the catalyst in a mixture can be determined by monitoring the rate of decrease in concentration of S or the rate of an increase in concentration of one of the products. It is preferable that the rate constant of uncatalyzed reaction, \( k_u \), is smaller than that of catalyzed reaction, \( k_c[M] \), in order to obtain high sensitivity and precise results.

### 3 INDICATOR REACTIONS

A large number of indicator reactions are used for the kinetic–catalytic methods in homogeneous systems. Nonenzymatic indicator reactions can be classified into two broad categories: (1) redox reaction and (2) ligand substitution and complex formation reactions.

#### 3.1 Redox Reactions

Redox reactions have frequently been used as the indicator reactions in kinetic–catalytic methods with spectrophotometric detection. Reactant S used in the redox reaction is an inorganic or organic compound, which is converted into a colored or colorless compound P by an oxidant and/or a reductant R. Oxidation reactions of organic compounds are likely to be used most frequently as the indicator reactions for the determination of metal ions based on their catalysis. The absorbance change of the reactant S and/or the product P is usually monitored. Typical organic compounds used in the indicator reactions are hydrogen peroxide, chlorate, bromate, peroxodisulfate, periodate and dissolved oxygen, and reductants such as ascorbic acid, hydrazine, hydroxylamine, hypophosphorous acid, alkali sulfides, thiosulfate and tin(II), etc. are also used. The role of oxidants is simply to regenerate the catalyst M. Although these oxidants have high oxidation potential for oxidizing S to P, the oxidation rate is very slow, and the regeneration process of M' to M proceeds very rapidly. The concentration of catalyst M is kept constant during the reaction, as a result of the regeneration of M. Thus a trace amount of M can be determined. Typical examples of catalysts are metal ions such as iron(II, III), copper(I, II), manganese(II, IV, VII), vanadium(IV, V), cobalt(II, III), chromium(III, VI) and nonmetal ions such as iodide and bromide.

CL processes are closely related to redox reactions. Generally, CL is observed in a redox reaction which yields an electronically excited product; it emits luminescence or transfers its energy to another luminescent molecule present.\(^{19,40}\) As shown in Figure 2, commonly used reagents for the CL reactions are acyl hydrazides (e.g. luminol), acridine derivatives (e.g. lucigenin), imidazoles (e.g. lophine) and peroxyoxalates (e.g. bis(2,4,6-trichlorophenyl) oxalate (TCPO) and bis(2,4-dinitrophenyl) oxalate (DNPO)).

Of these, luminol (5-meric—2,3-dihydro-1,4-phenathalazinedione) is widely used in the CL reactions. The CL reaction of luminol was first reported by Albrecht in 1928\(^{41}\) and involves the oxidation of luminol by oxidants such as oxygen, hydrogen peroxide, hypochlorite, persulfate, and so on in an alkaline solution.\(^{42,43}\) The CL reaction of luminol with hydrogen peroxide has been...
KINETIC DETERMINATIONS

known as one of the most sensitive systems in analytical use and has been applied for the determination of metal ions such as cobalt(II), copper(II), chromium(III), iron(II) and so on, at the nanogram level. In addition, the luminol/H$_2$O$_2$/hexacyanoferate(III) system has been widely used for the determination of hydrogen peroxide and biosubstances.

Lucigenin (10,10'-dimethyl-9,9'-biacridinium dinitrate) is the second most popular CL reagent and its CL properties were first observed by Glue and Petsch in

Figure 1 (Continued)

![Chemical Structures](image)

Figure 2 Representative CL compounds and their postulated schemes. I, luminol; II, lucigenin; III, lophine; IV, TCPO (F denotes a fluorophore).
1935.\(^{(44)}\) The oxidation of lucigenin occurs with peroxide under alkaline media to produce a blue light emission as well as a green luminescent light when a catalyst, e.g. heavy metal ion, is present. This blue light is spectrally the same as the fluorescent light of the oxidized product of lucigenin, \(N\)-methylacridone.\(^{(43)}\) As \(N\)-methylacridone is insoluble in water, a micellar system containing a suitable surfactant is used to solubilize the precipitate.\(^{(45)}\) There are a large number of analytical applications of the CL reaction of lucigenin for the determination of metal ions. The CL of lophine (2,4,5-triphenylimidazole) was first discovered by Radzisewski in 1877.\(^{(46)}\) The CL reaction of lophine involves the initial oxidation of the lophine anion to its free radical, reaction of the radical with molecular oxygen to give a peroxide, and reaction of the peroxide with base to yield light.\(^{(47)}\) The oxidation reaction of lophine is also catalyzed by various transition metal ions in the presence of suitable oxidants.

Peroxoyxalate CL involves its oxidation with hydrogen peroxide to produce an energy-rich intermediate. This metastable intermediate can provide enough chemiexcitation energy for the production of an excited state fluorophore. Through the production of a charge transfer complex between the intermediate and a fluorophore, the actual chemiexcitation step occurs. This charge transfer complex dissociates to produce the chemically excited fluorophore which returns to the ground state via emission of a photon.\(^{(48)}\)

### 3.2 Ligand Substitution and Complexation Reactions

Kinetic–catalytic determinations not involving redox reaction processes have also been developed by many authors. An example of this category is the substitution of ligands and/or metal ions in metal complexes. This reaction is homogeneously catalyzed by minute amounts of relatively soft metal ions such as mercury, cadmium as well as ammonia and some other species.

A substitution reaction of one ligand by another \(L\) in a metal complex maximum absorbance (MA) or MAX and a double exchange reaction between \(M_1L\) and \(M_2X\) are widely used in kinetic–catalytic methods, according to the general scheme shown in Equations (7–9):

\[
\begin{align*}
MA + L &\longrightarrow ML + A & (7) \\
MAX + L &\longrightarrow ML + A + X & (8) \\
M_1L + M_2X &\longrightarrow M_1X + M_2L & (9)
\end{align*}
\]

An example of Equation (7) is the reaction of hexacyanoferrate(II) with \(p\)-nitrosodiphenylamine (\(p\)-NDA) in aqueous solution, which is catalyzed by mercury(II), Equation (10).\(^{(49,50)}\)

\[
\text{Fe(CN)}_6^{4-} + p\text{-NDA} \longrightarrow \text{Fe(CN)}_5 \cdot p\text{-NDA}^{3-} + \text{CN}^- \quad (10)
\]

The concentration of the green product, \([\text{Fe(CN)}_5 \cdot p\text{-NDA}^{3-}] (\lambda_{\text{max}} = 640 \text{ nm})\), is proportional to the amount of mercury(II) present in a solution at a fixed time. The determinable range for mercury(II) is \(1 \times 10^{-7} - 1 \times 10^{-6}\) M.

An example of Equation (9) is the exchange reaction between triethylenetetraminonickel(II) (\(\text{NiT}^{2+}\)) and ethylenediaminetetraacetocuprate(II) (\(\text{CuY}^{2-}\)), which is catalyzed by EDTA (ethylenediamine-\(N,N,N',N'\)-tetraacetic acid) or Trien (triethylenetetraamine) and is inhibited by any metal ions complexing these ligands.\(^{(51,52)}\) Equation (11)

\[
\text{NiT}^{2+} + \text{CuY}^{2-} \longrightarrow \text{CuT}^{2+} + \text{NiY}^{2-} \quad (11)
\]

The exchange rate is monitored by measuring the absorbance of \(\text{CuT}^{2+}\) as a function of time. Trace amounts of EDTA (\(10^{-7} \text{ M levels}\)) and metal ions (\(10^{-8} \text{ M levels}\)) can be determined.

### 4 ACTIVATORS AND SURFACTANTS IN CATALYZED REACTIONS

Generally a catalyzed reaction proceeds more quickly than an uncatalyzed reaction with an increase in temperature and reaction time. However, the increase in temperature and time also increases the rate of uncatalyzed reaction. It is possible to increase the sensitivity of kinetic–catalytic methods by the application of activators and/or surfactants.

#### 4.1 Activators

An activator is defined as a substance that does not catalyze the indicator reaction, Equation (2), but increases its rate in the presence of a catalyst. The use of activators also provides greater selectivity in kinetic–catalytic methods. According to Bontchev,\(^{(6)}\) activators are classified into three groups depending on the role of the catalyst in the reaction, the nature of the catalyst–activator interaction and the stage of the reaction affected in the presence of the activator:

1. activators affecting the catalyst–substrate interaction
2. activators participating in the regeneration of the catalyst
3. activators acting indirectly in the catalytic process

Generally, activation effects are limited to metal-catalyzed reactions and connected to the complex-forming tendency of metal ions. Furthermore, the dependence of the rate of the reaction on activator concentration shows a maximum. Such a maximum is a characteristic feature of all types of activator which are concerned
with the formation of ternary complexes of the type activator–metal–substrate. Thus, the coordination sphere of the catalyst is fully occupied by the activator and any complexation with substrate does not occur at higher concentrations of activator. For example, 1,10-phenanthroline (phen) and 2,2′-bipyridine (bpy) act as effective activators for the catalysis of iron(III), manganese(II) and copper(II) in the indicator reactions and the dependency of the concentration of these activators shows a maximum. 5-Sulfosalicylic acid, tartaric acid and 1,2-dihydroxy-3,5-benzenedisulfonic acid (Tiron) act as effective activators for vanadium(V)-catalyzed reactions. EDTA acts as an effective activator only for the chromium(III)-catalyzed reactions, although EDTA masks the catalysis of other metal ions.

4.2 Surfactants
Surfactant molecules associate dynamically to form assemblies such as micelles, reversed micelles and bilayer aggregates (lamella or vesicle structure). At concentrations above the critical micelle concentration (CMC) of surfactants, the following capabilities are expected:

1. solubilize, concentrate and organize reactants according to hydrophobic, electrostatic and specific interactions
2. alter the effective microenvironment, i.e. polarity, viscosity, acidity
3. alter the chemical pathways and reaction rates
4. alter the spectral parameters of solubilized chemical species
5. stabilize the chemical species with optical transparency.

These properties are of interest in analysis and can be used in kinetic–catalytic methods as well as in equilibrium-based ones. The use of organized surfactant molecular assemblies increases the sensitivity, selectivity and precision of the methods. For example, the copper(II)-catalyzed reaction between \( N,N \)-dimethyl-\( p \)-phenylenediamine (DPD) and DMA in the presence of hydrogen peroxide is enhanced by sodium dodecylsulfate (SDS) and dodecyltrimethylammonium bromide (DTAB) micelles. The DL and specificity of the copper(II) determination in the presence of SDS or DTAB are improved compared with those in their absence.

5 METHODS OF DETERMINATION
In order to determine the concentration of a catalyst or a reactant in solution by the kinetic-based method, the change in the physical property of the monitored species as a function of time must be measured and kinetic curves are needed.

The procedures for determining the catalyst concentration by measuring the rate of catalyzed reaction are the initial rate method (tangent method), fixed time method and variable time (fixed concentration) method. The induction period measurements are also applied to some catalytic reactions in which there is a time delay between reactants and the appearance of change in the chemical composition of the system.

Equation (6) can be simplified as follows, Equations (12) and (13):

\[
\frac{d[P]}{dt} = F_u + F_c[M] \quad (12)
\]
\[
\frac{\Delta[P]}{\Delta t} = F_u + F_c[M] \quad (13)
\]

where \( F_u \) and \( F_c \) are the conditional constants of uncatalyzed and catalyzed reactions, involving the concentrations of the reactants, respectively. These equations are the basis of determining the concentration of the catalyst.

5.1 Tangent and Initial Rate Methods
The rate of a reaction, \( v \), corresponds to the concentration of the catalyst as exemplified by Equation (14)

\[
v = \frac{d[P]}{dt} = F_u + F_c[M] \quad (14)
\]

The change in a physical property of a monitored species is observed continuously and recorded versus time (Figure 3a). The slope of the resulting straight line, \( \tan \alpha \), is a measure of the catalyst concentration, known as the tangent method. The plot of \( \tan \alpha \) versus the concentration of catalyst is employed as a calibration graph (Figure 3b). The initial rate of the reaction is also measured from the slope of kinetic curves; this approach is called the initial rate method. Although the measurement of the initial rate requires the kinetic curve, it has some advantages:

1. The reaction obeys pseudo-zero order kinetics with respect to the reactants, because these concentrations do not change appreciably.
2. The back reaction which contributes to the rate of overall reaction is virtually nonexistent, because the amount of product formed during the initial period is very small.
3. Complications arising from any side reactions are minimized during this period. Thus, the reproducibility and the selectivity of the initial rate procedure
Figure 3 Absorbance – time curves (a) and calibration curve for catalyst determination by the tangent method (b).

Figure 4 Absorbance – time curves (a) and calibration curve for catalyst determination by the fixed time method (b).

are better than those of a fixed time procedure. In addition, the use of the initial rate as a parameter can be obtained over a wider determinable range, i.e. two or three orders of magnitude.

5.2 Fixed Time Methods

This method involves the determination of a physical property corresponding to the concentration of a reactant or a product at a definite time after the initiation of the reaction. For the fixed-time method, Equation (13) can be rewritten as Equation (15):

$$\Delta[P] = (F_p + F_c[M])\Delta t \quad (15)$$

Figure 4(a) shows the kinetic curves in the absence and the presence of the catalyst and Figure 4(b) shows a plot of an absorbance at a fixed time versus the concentration of the catalyst. From the latter curve (calibration curve), the concentration of the catalyst can be determined.
5.3 Variable Time Methods

The time required to attain a constant change in composition may be measured. For the variable time method, Equation (13) can be rewritten as Equation (16):

\[
\frac{1}{\Delta t} = \frac{F_u + F_i[M]}{\Delta[P]}
\]  

(16)

From the kinetic curves shown in Figure 5(a), a plot of \(1/\Delta t\) as a function of \([M]\) (Figure 5b) is obtained and is used for the determination of the catalyst.

5.4 Measurements of Induction Period

Some reactions used in the catalytic methods are characterized by the occurrence of induction periods. Reactions of this type generally proceed in two or more stages. The product of the first slow stage behaves as reactants for the second and final stages. The concentration of the catalyst is obtained from the following relationships, Equations (17) and (18)

\[
[M] = \frac{\text{const}}{t_i}
\]

(17)

\[
[M] = \frac{\text{const}}{t_{i1}}
\]

(18)

where const denotes a conditional constant for a given reaction and \(t_i\) is an interval time of an induction period. Figure 6(a) shows typical absorbance versus time curves and Figure 6(b) shows a plot of \(1/t_i\) versus catalyst concentrations.

5.5 Analysis of Mixtures by Differential Rates

Differential reaction rate methods, based on the different rate at which two or more species interact with a common reagent, permit analysis of two or more species without prior separation.\(^{63}\) Although these methods are based on an uncatalyzed reaction, they are also applied to the determination of mixtures acting as catalyst for a given catalyzed reaction. Differential rate methods are classified into two categories depending on the approach used:\(^{26,27}\)

1. those based on graphical evaluations (e.g. logarithmic extrapolation method), and
2. those based on mathematical complications (e.g. proportional equation method).

An example is the simultaneous determination of Ru and Os based on their catalysis in the reaction of Ce(IV) with As(III).\(^{64}\) With concentrations of \(5 \times 10^{-3} \text{ M Ce(IV)}\) and \(1 \times 10^{-3} \text{ M As(III)}\), conditions prevailing for selectivity for ruthenium, the initial rate of the catalyzed reaction in 2 M H\(_2\)SO\(_4\) is given by Equation (19)

\[
v_1 = 240[\text{RuO}_4] + 90.4[\text{OsO}_4]
\]

(19)

With concentrations of \(5 \times 10^{-4} \text{ M Ce(IV)}\) and \(1 \times 10^{-3} \text{ M As(III)}\), the latter being added first, and conditions prevailing for selectivity for osmium, the resulting rate
equation is expressed as Equation (20):

\[ n_2^{2}D_2 = 69[RuO_4] + 78.0[OsO_4] \]  

By measuring the rates under these two sets of conditions, mixtures of RuO\(_4\) and OsO\(_4\) in the range \(2 \times 10^{-10} - 1 \times 10^{-7}\) M can be determined with relative standard deviations ranging 0.51–4.1%.

5.6 Flow-injection Analysis

Since kinetic methods include time as an experimental variable, care is needed in the mixing of reagents at regular time intervals to obtain highly accurate results. Furthermore, batch methods are sometimes time-consuming and laborious. Such disadvantages in the batch method can be overcome by using FIA, which is firmly established as a fast precise accurate efficient and extremely versatile analytical technique. The FIA method is a suitable technique for catalytic methods of analysis because the rate of the catalyzed reaction can easily be controlled by fixing the flow rate of the solutions and the length of the reaction coil, yielding reproducible mixing. The fundamental characteristic of FIA is its intrinsically kinetic nature. The adaptation of FIA to catalytic methods can lead to many advantages, namely rapid and reproducible mixing of sample and reagents solutions can be achieved in the closed flow system without any contamination from the environment and a large number of samples can be treated automatically in a short time.\(^{(65)}\) FIA procedures for trace elements using of kinetic–catalytic methods have been reviewed.\(^{(21)}\)

6 TITRIMETRIC METHODS WITH CATALYTIC END-POINT INDICATION

In 1960, Erdey and Buzas\(^{(66)}\) first reported the titration of EDTA with copper(II) employing copper(II)-catalyzed luminol and lucigenin CL as indicator reactions which were later studied in depth by Mottola.\(^{(67,68)}\) Since the appearance of this work, papers on titrimetric methods with catalytic end-point indication (catalytic titration) for the determination of inorganic and organic compounds have increased. Since 1960, about 200 papers on catalytic titrimetric procedures have been published for the determination of catalysts and other species by photometric, potentiometric, biamperometric and thermometric techniques.

The methodology involves two consecutive reactions, i.e. titration and indicator reactions. The titration reaction is expressed as Equation (21):

\[ L + M \rightarrow ML \]  

where L, M and ML are the titrated component (inhibitor), titrant (catalyst) and titration product (catalytically inactive), respectively.

As described in section 2, the indicator reaction is expressed as Equation (2):

\[ S + R \rightarrow P + Q \]  

A small excess of the titrant M added after the equivalence point catalyzes the indicator reaction and this
catalyzed reaction is used to detect the end-point of the titration. As previously noted, rapid regeneration of M by Equation (4) results in the catalytic formation of the product P, and thus trace amounts of M lead to marked color changes in the end-point of the solution titrated. It is thus possible to determine trace amounts of the catalyst M when a small excess of the titrant M is added to the known amount of the titrated component such as EDTA.

Some examples of the titrimetric methods for the determination of metals (catalyst) or inhibitors are compiled in Table 2.(67,69–81) Other interesting approaches are briefly reviewed below.

The oxidation of 1,4-dihydroxyphthalimide dioxime (DHOPO) by iodate is catalyzed by nickel(II); the oxidation product has an absorbance maximum at 510 nm. The indicator reaction is used for the determination of inhibitory substances such as EDTA and CDTA, and also for the indirect titration of nickel(II), mercury(II) and iron(III).(82) Amounts of EDTA and CDTA in the range 700–6000 µg. are determined.

A semiautomatic spectrophotometric method of endpoint indication for indirect catalytic titrations of alkaline earth ions has been developed.(83) The manganese(II)-catalyzed autoxidation of 1,4-dihydroxyphthalimide di-thiosemicarbazone is used as an indicator reaction. Calcium and magnesium (10–150 µg), strontium (20–250 µg), and barium (20–450 µg) can be determined by adding a known excess of EDTA to the sample solution and back-titrating the unconsumed inhibitor agent with standard EDTA and CDTA in the range 700–6000 µg. are determined.

A simple catalytic end-point indication has been developed for total concentrations of heavy metal ions which form more stable EDTA complexes than manganese(II). The method is based on the substitution reaction of manganese(II)–EDTA and heavy metal ions to produce manganese(II). The end-point is determined by the manganese(II)-catalyzed oxidation of Acid Blue 45 dye (1,5-dihydroxy-4,8-diaminoantraquinone-2,6-disulfonate) with hydrogen peroxide as a result of decoloration. The method is applicable to the determination of heavy metal ions in river and groundwater samples.

A semiautomatic spotting method is used for end-point detection.(86) In this method metal ion catalysts in the range 3–70 µg mL⁻¹ are titrated with EDTA. The necessary assembly consists of a titration vessel, mixing chamber, automatic syringe burette, PTFE (polytetrafluoroethylene)-coated belt (a moving band) and connection tubes. In an example copper(II) is visually determined by using a copper-catalyzed hydroquinone/hydrogen peroxide reaction in the presence of bpy as activator. The titration vessel is completely filled with a sample solution of copper(II) (avoiding gas bubbles). The reagent solutions for the indicator reaction are delivered to the mixing chamber from two automatic syringe burettes at a constant speed. After a few drops of the reagent, solutions leave the mixing chamber for the belt (which is not moving yet), the EDTA titrant is propelled to the titration vessel at a constant speed by the syringe burette. Simultaneously, the PTFE-coated belt starts to move at a constant speed. Because the titration vessel is completely filled with the sample solution, excess solution containing EDTA and copper(II) is pushed out of the titration vessel into the mixing chamber where the catalyzed reaction occurs. Before the end-point, the drops on the moving belt are red–brown caused by formation of products of the copper-catalyzed reaction; after the end-point, the drops are colorless. The first drop which shows a color change corresponds to the end-point. Calibration graphs are prepared by plotting titration time versus copper concentration.

The catalytic titration of aminopolycarboxylic acids (EDTA, GEDTA, CDTA and DTPA) using manganese(II) as a titrant and the manganese-catalyzed periodate–diethylamine reaction, which acts as an indicator reaction, has been developed to demonstrate the usefulness of flow injection pseudotitration in catalytic titrimetry.(87) The titrant and each reagent for the indicator reaction are mixed in a 100-cm mixing coil and the mixing chamber, and then allowed to react in a 3-m reaction coil. When an aminopolycarboxylic acid sample solution (200 µL) is injected into the reacting flowstream, the catalysis is inhibited by the formation of the manganese–aminopolycarboxylic acid complex, and the uncatalyzed reaction is monitored, resulting in the transmittance being increased from 3% to 75%. The FIA peak width depends on the aminopolycarboxylic acid concentration in the range 5 × 10⁻⁶–1 × 10⁻² M.

Raya-Saro and Perez-Bendito(73,74) reported a method for the simultaneous catalytic titration of binary mixtures of mercury(II) with copper(II) or cadmium at the micromolar level by using the oxidation of DBPT by hydrogen peroxide as an indicator reaction. Copper(II) and mercury(II) ions act as catalyst and inhibitor for the indicator reaction, respectively. The combination of the

a By the indirect back-titration method.

b Binary mixture.

c Two sample aliquots are necessary. Triethanolamine or fluoride was used as a masking agent for iron(III) in the determination of copper, nickel or manganese only.

d Copper(II) and mercury(II) act as a catalyst and an inhibitor, respectively. Cysteine has a counter-inhibitory effect on mercury. Cystine is reduced to cysteine by hydroxylamine. Two catalytic titration runs, in the absence and presence of hydroxylamine, are needed for each sample.

e In this method free mineral acids have been simultaneously determined with turbidimetric end-point indication.

f Amounts of the active ingredients (e.g. hyoscine butyl bromide, pyridostigmine bromide and neostigmine bromide).
catalytic effect of copper(II) and the inhibitory effect of mercury(II), along with the blocking of the catalytic cycle by EDTA are used as the basis for titrimetric methods for individual and simultaneous titrations of mercury and copper or cadmium, with catalytic end-point detection.

A gaseous catalyst (hydrogen sulfide) is also used for the end-point indication in titrimetric analysis of metal ions with the hydrogen sulfide-catalyzed iodine–azide reaction as an indicator reaction. Sodium sulfide can be used as a standard solution for the determination of metal ions such as antimony, nickel, iron, mercury plus cadmium, lead plus copper and silver plus copper (precipitation) and permanganate (redox reaction) both in acidic solution. Once the metal ions are fully precipitated or reduced by sodium sulfide, hydrogen sulfide is liberated and transferred by a stream of nitrogen gas into the separate indicator vessel containing the solution of sodium azide, iodine and starch. Thus the color of the solution disappears at the end-point.

7 KINETIC–CATALYTIC METHODS FOR TRACE ELEMENTS

A large number of publications devoted to kinetic–catalytic determination of trace elements that obtain higher sensitivity and better selectivity have been reported, with a marked trend toward its application to environmental, clinical, pharmaceutical and agricultural samples. The determination of a single species in a mixture is the most popular area of the kinetic–catalytic method. Relatively few methods are reported for the simultaneous determination of two components. This section describes the kinetic–catalytic determination for trace elements using redox and ligand substitution reactions.

7.1 Catalytic Methods Using Redox Reactions

Inorganic and organic redox reactions are extensively used for kinetic–catalytic methods. These methods focus on the determination of transition metal ions such as copper, cobalt, manganese, iron and vanadium. Tables 3–9 show selected methods.

DPKH, 2,2'-dipyridylketone hydrazone; HBAA, 3-hydroxybenzaldehyde azine; o-PDA, o-phenylenediamine; FMN, flavin mononucleotide; Py, pyridine.
based on catalyzed-redox reactions. Of these, spectrophotometry occupies a predominant position because of the wide use of colored organic compounds.

When the reactants of the indicator reaction have high absorptivity for monitoring the reaction rate, it is preferable to combine the catalyzed reaction with a second coupling reaction yielding a colored product. An oxidative coupling reaction of MBTH with DMA in the presence of H$_2$O$_2$ is used as an indicator reaction for the kinetic–catalytic determination of Cu(II),$^{58}$ Mn(II),$^{54,154}$ Co(II),$^{124}$ and Fe(II, III)$^{149}$ at nanograms per milliliter levels, Equations (22) and (23)

\[
\text{MBTH + DMA} + \text{M}^{(\sigma+1)+} \rightarrow \text{indamine dye} + \text{M}^\sigma
\]

(\lambda_{\text{max}} = 590 \text{ nm}) \hspace{1cm} (22)

In these reaction systems, the use of activators allows an increase in the sensitivity. Among them, catalytic effects of Cr(III) and Co(II) in the presence of activators are worthy of remark. EDTA acts as an activator for Cr(III), because the Cr(III)–EDTA complex catalyzes the decomposition of H$_2$O$_2$. On the other hand, Cr(VI) has hardly any catalytic action in this reaction because of the formation of a peroxochromium(VI) complex and slow production of Cr(III) from this complex.\(^{58}\)

In the Co(II)-catalyzed reaction system, the extremely high activating effect is obtained by using two activators,
Cu(II) in this system. A Cu(II) concentration as low as found that DAOS is the most sensitive reagent for Cu(II) presence of SDS at concentrations above its CMC.

The peak height in the presence of SDS is about eight times as high as that without it. By using modified Trinder’s reagents instead of DMA as a coupling agent for MBTH, the catalytic effect of Cu(II) and pyridine is selected as the most effective activator for Cu(II) in this system. A Cu(II) concentration as low as $10^{-11}$ M can easily be determined by using the fixed time procedure, and the method has been successfully applied to the copper determination in real samples.

The oxidative coupling of AA with DMA in the presence of bromate is used for the catalytic determination of V(IV) in the manual and FIA mode. In this reaction system, SSA and Tiron act as activators. The combination of this method and solvent extraction of vanadium with $N$-cinnamoyl-$N$-(2,3-xylyl)hydroxylamine (CXA) allows the differential determination of V(IV) and V(V) in natural waters.

Fluorimetry is an effective tool for monitoring the rate of reaction. However, these are fewer catalytic fluorimetric methods than spectrophotometric ones. Valcarcel et al. have reported catalytic methods based on fluorimetric reactions; the $H_2O_2$ oxidation of PPH and/or precipitates in the samples does not affect the other advantages; the presence of colored compounds and FIA procedures. For the determination of Cu(II) and Fe(II, III), hydrogen peroxide is used as an oxidant. Activators for Cu(II) and Fe(II, III) are ammonia and acetate, respectively. In the FIA determination, Tween 80 acting as a nonionic surfactant improves the sensitivity and sampling frequency. Concentrations of Cu(II) and Fe(II, III) at $10^{-7}$–$10^{-8}$ M levels can be determined from the increase in the absorbance of the product at a fixed time. For the V(V) determination, bromate and tartrate are used as an oxidant and an activator, respectively.

The oxidative coupling of AA with DMA in the presence of bromate is used for the catalytic determination of V(IV, V) in the manual and FIA mode. In this reaction system, SSA and Tiron act as activators. The combination of this method and solvent extraction of vanadium with $N$-cinnamoyl-$N$-(2,3-xylyl)hydroxylamine (CXA) allows the differential determination of V(IV) and V(V) in natural waters.

Fluorimetry is an effective tool for monitoring the rate of reaction. However, these are fewer catalytic fluorimetric methods than spectrophotometric ones. Valcarcel et al. have reported catalytic methods based on fluorimetric reactions; the $H_2O_2$ oxidation of PPH and/or precipitates in the samples does not affect the other advantages; the presence of colored compounds and/or precipitates in the samples does not affect the thermometric detection. On the basis of Co(II)-catalyzed oxidation of DHBA by $H_2O_2$, a thermometric determination of Co(II) is developed with the aid of a personal computer.

computer system.\(^{121}\) The calibration graph is linear in the range 1–16 ng mL\(^{-1}\) Co(II) and the method is applied to the pharmaceutical sample.

Thermal lens spectrometry (TLS) is 100–1000 times more sensitive than conventional spectrophotometry and is used for monitoring the rate of the bromate oxidation of aniline catalyzed by V(V) in the presence of 8-quinolinol or pyrocatechol as an activator.\(^{189}\) The DL of the TLS method is 100 times lower than that of the spectrophotometric method.

The oxidation of CL reagent with a suitable oxidant has been applied to the kinetic–catalytic determination of transition metal ions by many workers. CL methods have some advantages in simplicity of instrumentation, low limits of detection and a wide dynamic range. Further, the use of a CL reaction with FIA techniques allows rapid and reproducible determination. However, the application of the method to real samples is difficult because of its lack of specificity. Several separation procedures such as ion exchange, solvent extraction and a membrane phase separator are used prior to the determination of a catalyst as well as the use of a masking agent. A luminol CL reaction is utilized for the determination of transition metal ions by FIA with separation processes.\(^{128,151}\) The CL oxidation of gallic acid with H\(_2\)O\(_2\) is adopted for the flow-injection determination of Co(II) with an inline column of immobilized 8-quinolinol.\(^ {120}\) The method enables the determination of picomolar levels of Co(II) in seawater. The oxidation of brilliant sulfoflavine with H\(_2\)O\(_2\) is adapted for the CL–FIA determination of Fe(II).\(^{150}\) A cation column is used to preconcentrate the iron in seawater. The DL of the method is 0.45 × 10\(^{-9}\) M when 4.4 mL of sample is passed through the column.

There are several methods for the determination of anions containing nonmetals, although most catalytic determinations are intended to determine various metals.\(^ {26,27}\) Iodide ion can be determined by its catalytic effect on the redox reaction between As(III) and Ce(IV)

in sulfuric acid solution. This reaction proceeds very slowly, but traces of iodide increase the rate of the reaction. The rate of the reaction is proportional to the iodide concentration: the time required for the yellow color of Ce(IV) to disappear is inversely proportional to the amounts of iodide present in solution. The determination of iodide based on this reaction has been used extensively by many workers. This reaction system is applied to the FIA in the stopped-flow mode; the dynamic range of the FIA method is 46–460 ng mL⁻¹. Many differential kinetic methods based on uncatalyzed reactions have been proposed for the analysis of mixtures involving closely related compounds without prior separation. By using catalyzed reactions, a few methods for the simultaneous determination of two catalysts are reported; they are listed in Table 10. A method for the differential determination of Mo(VI) and W(VI) based on their different catalytic effects on the oxidation of chlorpromazine by H₂O₂ has been proposed. The initial rates at two different H₂O₂ concentrations and the corresponding rate equations are obtained; mixtures of Mo(VI) and W(VI) in the 10⁻⁷ M range can be determined. The method is applied to the

Tetrabase, 4,4'-bis(dimethylamino)diphenylmethane; PAPH, pyridine-2-aldehyde 2-pyridylhydrazone. Other abbreviations as in Tables 3–8.

determination of these ions in hot spring water. The simultaneous determination of these ions in a single kinetic run is of interest.

Principal component regression (PCR) has been employed in data processing of multicomponent analysis. Zhu et al.\(^{285}\) have developed a simultaneous determination of Os(VIII) and Ru(IV) based on their catalytic action on the reaction between As(III) and Ce(IV), applying PCR to calculate the concentration of each catalyst.

7.2 Catalytic Methods Using Ligand Substitution and Complex Formation Reactions

The catalytic determinations of some metal ions and inorganic anions using ligand substitution and complex formation reactions are shown in Table 11.\(^{285}\) The ligand substitution reaction of the Hg(II) complex of CAC with CDTA (Equation 24) is used for the catalytic determination of trace amounts of ammonia.\(^{285}\)

\[
\text{Hg}^{II} - \text{CAC} + \text{CDTA} \rightarrow \text{Hg}^{II} - \text{CDTA} + \text{CAC}
\]  

The rate equation for Equation (24) in the presence of ammonia is expressed as Equations (25) and (26):

\[
\frac{\text{d[Hg}^{II} - \text{CAC}]}{\text{dt}} = k_0[\text{Hg}^{II} - \text{CAC}]
\]  

and

\[
k_0 = k_1' + k_2'[\text{H}^+] + k_3'[\text{H}^+]\text{[NH}_3]\]

where \(k_1', k_2'\) and \(k_3'\) refer to conditional rate constants. This reaction path, corresponding to the third term on the right-hand side of Equation (26), is expressed as Equations (27) and (28):

\[
\text{Hg} - \text{CAC} + \text{NH}_3 \rightarrow \text{HgNH}_3 + \text{CAC}
\]

\[
\text{HgNH}_3 + \text{CDTA} \rightarrow \text{Hg} - \text{CDTA} + \text{NH}_3
\]

This provides the basis of the determination of ammonia. From the absorbance of Hg\(^{II}\)-CAC complex at a fixed time, the concentration of ammonia at micromolar levels can be determined. Interferences from cationic and anionic ions are avoided by distillation of ammonia at room temperature.

DPDKPH, dipyridyldiketone phenylhydrazone; SAT, salicylaldehyde thiosemicarbazone; DAP, 2,4-diaminophenol; PCV, pyrocatechol violet. Other abbreviations as in Tables 3–9.

The ligand substitution of Hg\(^{II}\)-4-(2-pyridylazo)resorcinol (H\(_2\)PAR) complex of CDTA is catalytically accelerated by a trace amount of iodide, Equation (29):

\[
Hg(PAR)_2^{2-} + HCDTA^{3-} + H^+ \rightarrow Hg(CDTA)^{2-} + 2HPAR^- 
\]

According to detailed studies of the kinetics and mechanism of the reaction,\(^{270}\) Hg(PAR)\(^{2-}\) dissociates to Hg(PAR) which then reacts with iodide to form a mixed ligand complex, Hg(PAR)I\(^-\), which is more reactive with CDTA than Hg(PAR). The rate-determining step is the dissociation of the PAR molecule from Hg(PAR), Hg(PAR)OH\(^-\) and Hg(PAR)I\(^-\). Iodide and hydrogen ions enhance the rate of the dissociation of PAR molecule by their electron donation. The rate equation of Equation (29) is given as follows, Equations (30) and (31):

\[
\frac{d[Hg(PAR)_2^{2-}]}{dt} = k_0[Hg(PAR)_2^{2-}][HCDTA^{3-}] 
\]

\[
k_0 = (k_1[H^+]) + k_2 + k_3[H^+][I^-][HPAR^-]^{-1} 
\]

From Equation (31), the conditional constant \(k_0\) is a linear function of the iodide concentration when PAR is present in large excess and the pH is constant. By measuring the absorbance change at 500 nm, up to \(2 \times 10^{-7}\) M iodide can be determined. The method is applied to rainwater after separation of interfering ions using a cation exchanger. From the kinetic investigation of the ligand substitution reaction between the Hg\(^{II}\)-PAR complex and CDTA together with the catalytic effect of some inorganic ligands on this reaction, the difference
in reactivity between sulfite or thiosulfate and sulfate is established; the differential kinetic determinations of sulfite and thiosulfate are designed from the observations. Sulfite up to 1.5 × 10⁻⁶ M and thiosulfate up to 7 × 10⁻⁷ M can be determined in the presence of 10⁴ and 2.5 × 10⁴-fold molar amounts of sulfate under the optimized conditions.

Catalytic determinations of Ag(I) and Hg(I) are proposed using ligand substitutions of cyano and aminocyan complexes of iron with chromogenic organic ligands such as phen,

change occurs. Mercury(II) also accelerates the complex formation of H$_2$TPPS with Ni(II), Co(II) and Cu(II). In the metallloporphyrin formation reaction catalyzed by metal ions, the ionic radius ($r$) of the metal ion acting as a catalyst is an important factor. Large metal ions such as Cd$^{2+}$ ($r = 95$ pm), Cu$^+$ ($r = 96$ pm), Pb$^{2+}$ ($r = 73$ pm) and Hg$^{2+}$ ($r = 114$ pm) give rise to an appreciable catalytic effect, while medium-sized ions like Cu$^{2+}$ ($r = 73$ pm) and Zn$^{2+}$ ($r = 75$ pm) exert hardly any catalytic effect.

In the formation of Mn$^{II}$ (TPPS) catalyzed by Cd(II), the following reaction paths are proposed from the mechanical study. Equations (33–35):

\[
\begin{align*}
\text{Mn(II)} + \text{TPPS} & \rightarrow \text{Mn}^{II}\text{TPPS} \text{ (slow)} \quad (33) \\
\text{Cd(II)} + \text{TPPS} & \nRightarrow \text{Cd}^{II}\text{TPPS} \quad (34) \\
\text{Cd}^{II}\text{TPPS} + \text{Mn(II)} & \rightarrow \text{Mn}^{II}\text{TPPS} + \text{Cd(II)} \text{ (fast)} \quad (35)
\end{align*}
\]

Cadmium(II), having a large ionic radius, will distort the configuration of the porphine core which favors the attack of porphine nucleus by Mn(II) from behind (Equation 34). After the incorporation of Mn(II) (Equation 35), Cd(II) is liberated and takes part in the formation of Mn$^{II}$TPPS. On the basis of this consideration, the catalytic determination of Cd(II) has been developed: as little as $10^{-7}$ M Cd(II) can be determined from the decrease in absorbance of TPPS using a fixed time procedure. Since lead(II) interferes with the determination, it needs to be separated from Cd(II) by coprecipitation with manganese(IV) oxide.

Mercury(II) and Pb(II) also act as catalysts for the complex formation of TPPS with Mn(II) (Equation 33) in the same way as Cd(II). The catalytic methods for the determination of Hg(II) and Pb(II) are constructed using this complex formation. After separation of metallic mercury by distillation, concentrations of Hg(II) as low as $10^{-8}$ M can be determined. To determine Pb(II), interferences from Hg(II) and Cd(II) should be avoided by the addition of hydroxylamine and cyanide. Lead(II) concentrations at $10^{-7}$ M levels can be determined.

Although the rate of complex formation of Cr(III) with a ligand such as chromazurol S and EDTA is slow, this reaction is catalytically accelerated in the presence of carbonate and/or bicarbonate. By using these systems, the anions can be determined by spectrophotometry. The catalytic effect of fluoride and sulfate on the complex formation of Zr(IV) with XO is utilized for the determination of these anions.

The vast development in kinetic methods is a result of improvements in the sensitivity and selectivity brought about by the use of catalyzed reactions. These have facilitated the determination of microconstituents in various types of samples by straightforward and inexpensive instrumentation.

The number of papers devoted to kinetic photometric determination continues to be high, with a marked trend towards the application of the methods development to real sample analyses. Methods focus on the determination of transition metal ions like copper, manganese and iron, and are based on their catalytic effects on redox reactions. Relatively few methods for the determination of nonmetals and organic compounds are reported.

**ACKNOWLEDGMENTS**

This article was inspired by Professor A. Meyers and the editors of *Encyclopedia of Analytical Chemistry*. During the writing of this manuscript, the constant encouragement and valuable advice of the editors have been given. We also wish to thank Managing Editor, Dr Adam Holyoake, for his encouragement and constructive comments on this manuscript.

CATALYTIC KINETIC DETERMINATIONS: NONENZYMATIC

1 INTRODUCTION

Modern kinetic methods have benefited from the development of sophisticated data treatment techniques, the increasing availability of inexpensive computers, and the tremendous advances in instrumentation that is able to provide reliable data. For many years, most kinetic-based methods have been performed under pseudo-first-order conditions, which use simpler mathematical procedures. This approach is simplification of the reaction mechanism, carried out with an excess of reagent concentration, and aims to produce a reduction in the reaction order. However, the effective exploitation of the analytical potential of kinetics determinations requires the processing, without simplifications, of the actual reaction mechanism. Several approaches, such as the fractional time method, can be applied to elucidate the rate equations from which the concentrations of the species involved in the reaction can be calculated as a function of time. The differential nature of rate equations is a particular characteristic of kinetic methods, and it makes necessary the use of numerical methods to integrate accurately the rate equations.

However, it is essential to know the main sources of error in data treatment in order to reduce their effects on the results. Stress is put on the analysis of the errors due to the simplification of complex models. The different factors that influence the kinetics of the reaction are reviewed. How to take advantage of the kinetic information contained in the experimental data with an analytical aim is described. Finally, the propagation of errors in the analytical results is studied, reviewing both the simple univariate methods, used to determine one species, as well as the complex multivariate methods devoted to the determination of multicomponent mixtures.
kinetics is to induce from experience a chemical model, the reaction mechanism, explaining how the reaction takes place, and to develop a suitable mathematical model, the rate law, explaining the concentration variation with time of all chemical species of the reacting system.

Analytical chemists are mainly interested in the methodology of formal kinetics, since the mechanism of a reaction and the rate law should be known prior to their usage as an analytical tool.

2.2 The Reaction Rate

Let us suppose a reaction taking place according to the stoichiometric equation shown in Equation (1):

\[ v_A A + v_R R \rightarrow v_P P \]  

where A and R are reactants and P the product. The rate of such a process in a closed reactor is defined in Equation (2) as the variation with time in the number of moles generated by the chemical reaction:

\[ v = \frac{1}{v_i} \frac{1}{V} \frac{dn_i}{dt} \]  

where \( n_i \) is the number of moles of species \( i \), \( V \) the reactor volume, and \( v_i \) the stoichiometric coefficient, which is taken as positive for products and negative for reactants to ensure the positive sign of the reaction rate. The introduction of \( v_i \) and \( V \) makes the above definition independent of the chemical species used to follow the reaction, and on the reacting system size, respectively. Equation (2) turns into the usual definition of reaction rate, when volume remains constant during the reaction as shown in Equation (3):

\[ v = \frac{1}{v_i} \frac{1}{V} \frac{d n_i}{d t} = \frac{1}{v_i} \frac{d c_i}{d t} \]  

where \( c_i \) is the concentration of the \( i \)th reactant. Strictly speaking, the volume remains constant only for gas reactions taking place in a closed rigid reactor. For reactions in solution, Equation (3) does not stand exactly, since the volume of the reaction mixture depends on composition and, consequently, on time. Nevertheless, the volume can be considered as a constant for dilute solutions reacting isothermally. On the other hand, most of the physical properties used to follow the kinetics of a reaction depend linearly on the molar concentration of species.

2.3 The Rate Law

Reactions can be divided into elementary and complex according to their kinetic mechanism. An elementary reaction takes place in a single step through a unique transition state. The transition state is the complex formed by the reactants to achieve the products. Figure 1 illustrates the energy changes during this process. There is an energy barrier to the reaction because reactants must take energy to form the transition state. The difference in energy between the transition state and the reactants is called the activation energy. On the other hand, complex reactions consist of two or more elementary steps.

The rate law relates the reaction rate with system composition (at constant temperature and pressure), and its mathematical form can be established from stoichiometry only for elementary reactions. According to the Law of Mass Action, the general rate equation of an elementary reaction is shown by Equation (4):

\[ v = \frac{1}{v_i} \frac{1}{V} \frac{d c_i}{d t} = k \sum_{i=1}^{M} c_i^{v_i} \]  

where \( k \) is the rate constant (or specific rate) of the reaction, \( M \) the number of reactants, and \( v_i \) is taken as positive. The rate constant depends on pressure, on temperature, and, for reactions taking place between ions, on electrolyte concentration.

For complex reactions, the comprehensive experimental work carried out in chemical kinetics from the beginning of the 20th century allows the rate laws to be classified into simple and complicated.

A simple rate law can be expressed, in a similar manner to elementary reactions, by Equation (5):

\[ v = \frac{1}{v_i} \frac{1}{V} \frac{d c_i}{d t} = k \sum_{i=1}^{M} c_i^{v_i} \]  

Figure 1 Potential energy–reaction coordinate diagram for a hypothetical elementary reaction. (The final energy is not always lower than the initial energy.)
where $\gamma_i$ is the reaction order with regard to the $i$th reactant. The reaction orders are empirical parameters induced from experience and whose values coincide with the stoichiometric coefficients only for elementary reactions. The sum of the reaction orders is the overall order of the reaction. For reactions with simple rate laws, the change of concentrations with time can be described by a single extent of reaction. The study of the kinetics of a single reaction is reduced to calculating $k$ and the reaction orders.

### 2.4 The Mechanism of Reaction and the Rate Law

As previously stated, elementary reactions take place through a unique transition state and their rate law can be easily established. However, most chemical reactions are not elementary, and must be described by a reaction mechanism, which shows how the reaction takes place and must include all the contributing elementary reactions and the intermediate species formed. Thus, the reaction mechanism is the chemical model associated with a reaction while the rate law is the associated mathematical model. Once the mechanism is postulated, the mathematical model, which consists of an ordinary differential equation (o.d.e.) system, can be easily derived. Each differential equation of the system is the global derivative of the species concentration with regard to time, which is obtained by summation over the reaction rates of the elementary reactions where the species takes part, multiplied by its stoichiometric coefficient.

Let us consider, as an example, a simple enzyme-catalyzed reaction with the stoichiometry shown in Equation (6):

$$E + S \xrightarrow{k_1} ES \xrightarrow{k_2} E + P$$  (6)

where $E$ is the enzyme and $S$ the substrate. Equation (7) is the simplest kinetic mechanism that can account for this reaction with three elementary steps:

$$E + S \underset{k_{-1}}{\xrightarrow{k_1}} ES \xrightarrow{k_2} E + P$$  (7)

where $ES$ is an enzyme–substrate complex. From this mechanism, it is possible to build the differential equation system shown in Equations (8–11):

$$\frac{d[E]}{dt} = -k_1[E][S] + k_{-1}[ES] + k_2[ES]$$  (8)

$$\frac{d[S]}{dt} = -k_1[E][S] + k_{-1}[ES]$$  (9)

$$\frac{d[ES]}{dt} = k_1[E][S] - k_{-1}[ES] - k_2[ES]$$  (10)

$$\frac{d[P]}{dt} = k_2[ES]$$  (11)

The concentration of species is obtained by integration of the o.d.e., but most o.d.e. systems do not have analytical solutions and must be integrated numerically. However, taking into account the relative rate at which the elementary reactions occur, sometimes the mathematical model can be simplified. The most popular simplifications arise from the use of the steady-state and the pre-equilibrium state hypotheses, together with the assumption of the existence of a rate-limiting step.

#### 2.4.1 Steady-state Hypothesis

Usually, reactions proceed through highly reactive species such as free radicals, ions, or reaction sites on the surface of a catalyst or enzymes. Owing to the intrinsic instability of these intermediates, their concentration will tend to remain low and constant compared to those of reactants and products. These facts are the basis of the steady-state hypothesis, in which the accumulation rate of a highly reactive intermediate is considered null and its associated differential equations equal to zero. Thus, its o.d.e. becomes an algebraic equation that allows the steady concentration of the intermediate to be related to the concentration of reactants and products. Since the concentration of the highly reactive intermediate remains low compared to that of reactants and products, it can be neglected in the concentration balances.

Steady-state hypothesis is often used to simplify enzymatic catalysis data treatment because once the steady state is accomplished for the enzyme–substrate complex, $ES$, the differential Equation (10) turns into the algebraic equation shown in Equation (12):

$$k_1[E][S] - k_{-1}[ES] - k_2[ES] = 0$$  (12)

This equation allows us to express the $ES$ concentration as a function of the reactant concentrations:

$$[ES] = \frac{k_1}{k_{-1} + k_2} [E][S]$$  (13)

The overall reaction rate is determined by the product formation rate and after substituting Equation (13) into Equation (11), it yields Equation (14):

$$\nu = \frac{d[P]}{dt} = k_2[ES] = \frac{k_2k_1}{k_{-1} + k_2} [E][S]$$  (14)

This solution will be valid as long as the steady-state approximation remains valid. At the beginning of the reaction this hypothesis cannot be applied because the concentration of the intermediate is building up from its initial value of zero to the steady-state value.

#### 2.4.2 Rate-limiting and Pre-equilibrium Steps

The reaction rate of the elementary steps of a mechanism can be very different. When there is a step much slower
than the others, it controls the rate of the overall reaction and the formation rate of final products equals the rate of this step, that is called the rate-limiting step. On the other hand, some mechanisms exhibit a rate-limiting step preceded by a fast reversible step. Then, it can be considered that the fast reversible step reaches the equilibrium being unperturbed by the following much slower step. Now the concentration of the intermediate can be obtained by solving the equilibrium equation. A system of this type is said to possess a fast pre-equilibrium step. Proton transfers constitute a very important class of fast pre-equilibrium steps as in acid-catalyzed reactions. Pre-equilibria steps can be found in other catalyzed reactions. One simple mechanism often encountered is shown in Equations (15) and (16):

\[
R + C \rightleftharpoons RC \\
RC + A \xrightarrow{k_c} P + C
\]

(15) (16)

where the first step is a fast equilibrium and the second the rate-limiting step, \(k_c\) being the catalytic rate constant and C the catalyst. The reaction rate is given by Equation (17):

\[
v = \frac{d[P]}{dt} = -\frac{d[A]}{dt} = k_c[RC][A]
\]

(17)

The concentration of the intermediate complex, RC, can be obtained by applying the pre-equilibrium hypothesis as shown in Equation (18):

\[
K = \frac{[RC]}{[R][C]} \rightleftharpoons [RC] = K[R][C]
\]

(18)

from which the rate law can be given by Equation (19):

\[
v = k_cK[R][C][A]
\]

(19)

Therefore, many complex reactions exhibit simple rate laws when the steady-state or the pre-equilibrium and limiting reaction steps hypothesis can be applied.

### 2.5 Determination of Simple Rate Laws

Most of the reactions of analytical interest follow the rate law given by Equation (5) after applying the steady-state or rate-limiting step approximations to the o.d.e. derived from their mechanisms. Generally, the study of the kinetics of a reaction involves measurement of a physical property like those summarized in Table 1. For this reason, it is convenient to express the rate law as a function of the measured physical property.

#### 2.5.1 Expression of the Concentrations as a Function of a Physical Property

Let us assume that the kinetics of a reaction is monitored by measuring a physical property \(S(t)\) that is a linear function of the composition of the reaction mixture given by Equation (20):

\[
S = S_b + \sum_{i=1}^{N} s_i c_i
\]

(20)

where \(N\) is the number of species in the system, \(S_b\) is the property measured from the blank and \(s_i\) is the proportionality coefficient between the concentration of the \(i\)th species and the physical property; the values of these constants can be estimated from equilibrium experiments when possible. The \(s\) coefficients are supposed to be independent of time and composition. If the rate law of the reaction is simple, the concentration variations will be described by a single extent of reaction, \(\xi\), according to

The property is not always linear...
Equation (21):
\[ c_i = c_{0,i} + v_i \xi \]  
\[ (21) \]
where \( c_{0,i} \) is the initial concentration of \( i \)th species. The substitution of Equation (21) into (20) yields:
\[ S = S_0 + \sum_{i=1}^{N} s_i (c_{0,i} + v_i \xi) \]
\[ = \left[ S_0 + \sum_{i=1}^{N} s_i c_{0,i} + \sum_{i=1}^{N} s_i v_i \xi \right] = S_0 + S^0 \xi \]  
\[ (22) \]
where \( S_0 \) is the property value at zero time. From Equations (21) and (22), Equation (23) can be obtained:
\[ \xi = \frac{S - S_0}{S^0} = \frac{c_i - c_{0,i}}{v_i} \]  
\[ (23) \]
At the end of the reaction, it becomes Equation (24):
\[ \frac{S_\infty - S_0}{S^0} = \frac{c_{\infty,i} - c_{0,i}}{v_i} \]  
\[ (24) \]
where \( c_{\infty,i} \) is the concentration of the \( i \)th species when the reaction has finished, and \( S_\infty \) the signal value at infinite time. From Equations (23) and (24), we obtain Equation (25):
\[ \alpha = \frac{c_i - c_{\infty,i}}{c_{0,i} - c_{\infty,i}} = \frac{S_\infty - S}{S_\infty - S_0} \]  
\[ (25) \]
Let us call A the limiting reactant for which the final concentration, \( a_\infty, \) is zero, then Equation (25) gives:
\[ \alpha = \frac{a}{a_0} = \frac{S_\infty - S}{S_\infty - S_0} \]  
\[ (26) \]
Equation (26) is the basis of the data treatment of simple rate laws, because they can be expressed as a function uniquely of the \( \alpha \) variable. It is important to realize that \( \alpha \) is a dimensionless number ranging from 0 to 1, and that it depends directly on the signal value.

2.5.2 First-order Reactions

For an elementary first-order reaction the stoichiometric equation will be given by Equation (27):
\[ A \xrightarrow{k} P \]  
\[ (27) \]
and the corresponding differential rate equation by Equation (28):
\[ \frac{da}{dt} = -ka \]  
\[ (28) \]
where \( a \) is the concentration of reactant A at time \( t \). After separating variables, this equation can be integrated as in Equation (29):
\[ \frac{a}{a_0} \frac{da}{t} = -k \]  
\[ (29) \]
where \( a_0 \) is the concentration of reactant A at time zero. The integration yields Equation (30):
\[ \ln \left( \frac{a}{a_0} \right) = -kt \]  
\[ (30) \]
Finally, first-order reactions are characterized by a semi-reaction time \( t_{1/2}, \) time needed to decrease the initial concentration of limiting reactant to half of its initial value) independent of the initial composition of the mixture, as shown in Equation (32):
\[ t_{1/2} = \frac{\ln(2)}{k} \]  
\[ (32) \]
Many of the reactions of analytical interest can be treated as first-order reactions when experimental conditions are chosen adequately. For instance, a second-order reaction between reactants A and R behaves as a first-order reaction when one of the reactants, R, is present in excess \([R] \gg [A]_0\) as shown in Equations (33) and (34):
\[ A + R \xrightarrow{k_2} P \]  
\[ (33) \]
\[ v = k_2[R][A] \xrightarrow{[R] \gg [A]_0} v \approx k_2[R]_0[A] = k_1[A] \]  
\[ (34) \]
In this case, we say that the second-order reaction has been transformed into a pseudo-first-order reaction. The ability to reduce the reaction order is a very valuable experimental tool, that often permits the simplification of the reaction kinetics.

2.5.2.1 Calculation of the Rate Constant

The determination of the rate law for first-order reactions reduces to the calculation of the rate constant. The fitting of experimental data to Equation (35):
\[ \ln(|S_\infty - S|) = \ln(|S_\infty - S_0|) - kt \]  
\[ (35) \]
gives the rate constant from the slope and, from the intercept, the initial concentration can be obtained. However, this method is not applicable when the final property cannot be accurately measured. This is the case for very slow reactions for which it is not
valuable to wait for completion, or when there are slow secondary processes which make it difficult to know the exact contribution of the main reaction to the value of $S_{\infty}$. In such cases, it is recommended to use the methods developed by Guggenheim or Kezky–Mangerlsdorf–Swinbourne (KMS).

For both methods the physical property is measured at two time series, $\{t_1, t_2, \ldots\}$ and $\{t_1 + \Delta t, t_2 + \Delta t, \ldots\}$, where $\Delta t$ is a constant time increment. The Guggenheim method takes the differences between the physical properties measured in both series as shown in Equation (36):

$$S(t + \Delta t) - S(t) = (S_{\infty} - S_0)(1 - e^{-k\Delta t})e^{-kt}$$  \hspace{1cm} (36)

This expression can be linearized by taking logarithms on both sides of the equation to give Equation (37):

$$\ln[S(t + \Delta t) - S(t)] = -kt + \ln[(S_{\infty} - S_0)(1 - e^{-k\Delta t})]$$  \hspace{1cm} (37)

Thus, a fit of the logarithm of the difference in the physical property values versus time should give a line, from whose slope the rate constant can be calculated. In the least-squares fitting of Equation (37) it is recommended to use the weight as in Equation (38):

$$w(t) = [S(t + \Delta t) - S(t)]^2$$  \hspace{1cm} (38)

to correct the perturbation due to the logarithm linearization.

The KMS method relates directly the data of both series, avoiding the signal difference calculation, as in Equation (39):

$$S(t + \Delta t) = S(t)e^{-k\Delta t} + S_{\infty}(1 - e^{-k\Delta t})$$  \hspace{1cm} (39)

Thus, a plot of $S(t + \Delta t)$ versus $S(t)$ yields a line with slope equal to $e^{-k\Delta t}$, from which it is possible to calculate the rate constant. In both methods the value of the time increment is an important factor, as illustrated in Figure 2. If $\Delta t$ is small, the relative error in the signal difference will be large; on this basis, $\Delta t$ should be as large as possible. However, the larger $\Delta t$ the smaller the number of data points used; then, an intermediate $\Delta t$ must be taken. It is recommended to take $\Delta t$ between $t_{1/2}$ and $2t_{1/2}$.

Finally, data can be fitted to Equation (31) directly using a nonlinear method. In this case $k$, $S_0$ and $S_{\infty}$ are adjustable parameters.

### 2.5.3 General Data Treatment for Simple Rate Laws

Let us suppose a reaction takes place according to Equation (1), and following the simple rate law given by Equation (40):

$$\frac{1}{v_A} \frac{da}{dt} = \frac{1}{v_R} \frac{dr}{dt} = -kd^p q^q$$  \hspace{1cm} (40)

where the stoichiometric coefficients are taken as positive, and $p$ and $q$ are the reaction orders with regard to the limiting reactant $A$ and the co-reactant $R$, respectively. According to Equation (21), the concentrations of $A$ and $R$ are related by Equation (41):

$$r = r_0 - \frac{v_R}{v_A}(a_0 - a) = r_\infty + \frac{v_R}{v_A}a$$  \hspace{1cm} (41)

The substitution of Equation (41) into Equation (40) leads to Equation (42):

$$\frac{da}{dt} = -v_A ka^p r^q\left(r_\infty + \frac{v_R}{v_A}a\right)$$  \hspace{1cm} (42)

This equation is commonly expressed as a function of the $a$ variable defined in section 2.5.1. Taking into account that $a = a/a_0$ yields Equation (43):

$$\frac{da}{dt} = -(v_A ka_0^{p+1}q^q)\left(r_\infty + \frac{v_R}{v_A}a\right)^q$$  \hspace{1cm} (43)

The benefits of this change of variable are evident; since we know how to relate the $a$ value to a physical property, it will be possible to fit directly the measured property expressed in terms of $a$. In addition, the resulting differential equation has the dimensionless $a$ as a unique variable, and analytical solutions for a large number of reaction orders, $p$ and $q$, are tabulated.(3) Now, the rate law will be determined when the parameters $k$, $p$ and $q$ are known. Indeed, the rate law depends on the ratio of the stoichiometric coefficients; thus the study of the stoichiometry of the reaction must be done prior to the kinetic study. The objective of the next section is to give a review of methods allowing the determination of $k$, $p$ and $q$. 

\[\text{Figure 2 Average relative error (percentage) in the evaluation of a first-order rate constant (}k=1\text{s}^{-1}\text{) using the Guggenheim (•) and KMS (○) methods, versus the }\Delta t \text{ used.}\]
2.5.4 Determination of the Reaction Orders and the Rate Constant

2.5.4.1 The Fractional Time Method  The fractional time method\(^{(3)}\) makes it possible to estimate the reaction orders and the rate constant from two kinetic experiments, one with the reactants being present initially at the stoichiometric ratio \(r_i = \alpha_i = 0\), and the other carried out with excess of one of the reactants \((r_0 \gg a_0\), then \(r_\infty/a_0 \gg \alpha\)). In these cases, Equation (43) reduces to:

\[
\frac{\mathrm{d}a}{\mathrm{d}t} = k^*a^m
\]  
(44)

where \(k^*\) is a constant and \(m = p + q\) in the first case, or \(m = p\) in the second. The integration of Equation (44), when \(m \neq 1\), leads to Equation (45):

\[
\frac{1}{1-m}(1 - a^{1-m}) = k^*t
\]  
(45)

This method takes a series of pairs \((t_i, \alpha)\) covering a wide interval of \(\alpha\) values [for instance \(\alpha \in (0.1, 0.95)\)], as shown in Equation (46):

\[
\alpha_1 = f\alpha_0, \alpha_2 = f\alpha_1, \ldots, \alpha_j = f\alpha_{j-1}, \ldots, \alpha_n = f\alpha_{n-1}
\]  
(46)

where \(f\) is a constant in the interval \(0 < f < 1\). Very often, some values will not be available because no measurements have been done, and, consequently, they will have to be interpolated, for instance by using the orthogonal polynomial method.\(^{(4)}\)

Equation (47) shows the difference between two consecutive values of \(\alpha\), deduced from Equation (45):

\[
\frac{1}{1-m} \alpha_{j-1-m} - \alpha_j^{1-m} = k^*(t_j - t_{j-1})
\]  
(47)

which can be rearranged to Equation (48):

\[
\alpha_j^{1-m} \frac{1 - f^{m-1}}{k^*(1-m)} = (t_j - t_{j-1})
\]  
(48)

On taking logarithms this leads to Equation (49):

\[
\ln(t_j - t_{j-1}) = \ln(1 - f^{m-1}/k^*(1-m)) + (1-m)\ln(\alpha_j)
\]  
(49)

A plot of the logarithm of \(t_j - t_{j-1}\) versus the logarithm of \(\alpha_j\) should yield a line whose slope and intercept give information on the value of \(m\) and the rate constant, respectively. Once the global order \(p + q\) and the partial order \(q\) are known, the partial order \(p\) can be obtained by difference.

2.5.4.2 The Initial Rate Method  The differential methods use the derivative of the physical property with respect to time, instead of the signal itself. The differential methods that use all the information \((t, S)\) available are rarely applied because the numerical differentiation of all signal profile could increase remarkably the noise level. Nevertheless, the last affirmation is no longer true for experimental kinetic methods that measure the reaction rate directly as the electrochemical amperometric monitoring of an electrode reaction. An advantage of differential methods is that they do not need to integrate any differential equation since the reaction rates are dependent on the composition of the system through an algebraic equation system.

The initial rate method is a differential method that uses, as a dependent variable, the reaction rate at zero time, at which the composition of the system is known. Let us assume a reaction is taking place according to Equation (1). If the rate law is simple, the initial reaction rate is as shown in Equation (50):

\[
v_0 = k_0 a_0^p b_0^q
\]  
(50)

where the subscript “0” refers to zero time. Taking logarithms on both sides of the expression leads to Equation (51):

\[
\ln(v_0) = \ln(k) + p \ln(a_0) + q \ln(b_0)
\]  
(51)

In this equation there are three parameters, \(k, p\) and \(q\); thus it is necessary to measure at least three reaction rates to determine them by fitting Equation (51). The experimental design should be such that one initial concentration is kept constant whereas the other is changed and vice versa. In this way each set of data can be related independently to parameters \(p\) and \(q\).

The correct evaluation of the initial rate is an important question. It can be estimated as the ratio between the variation of the signal and the interval of time elapsed at the beginning of the reaction. Therefore, for a first-order reaction given by Equation (52):

\[
v_0^\text{est} = \frac{S_2 - S_1}{t_2 - t_1} = \frac{(S_\infty - S_0)e^{-kt_2} - e^{-kt_1}}{t_2 - t_1}
\]  
(52)

The error associated can be calculated by means of a Maclaurin series expansion of the exponential term, shown in Equation (53):

\[
e^{-kt} = 1 - kt + \frac{1}{2}(kt)^2 - \cdots = \sum_{i=0}^{\infty} (-1)^i \frac{(kt)^i}{i!}
\]  
(53)

Since \(kt\) is close to zero near the origin, only the first three terms can be used, as shown in Equation (54):

\[
v_0^\text{est} \cong (S_\infty - S_0)k \left(1 + \frac{kt_1 + kt_2}{2}\right)
\]  
(54)
The exact initial rate can be evaluated by differentiating Equation (31) as shown in Equation (55):

\[ v_0 = \frac{dS}{dt} \Big|_{t=0} = (S_\infty - S_0)k \]  

(55)

Finally, the relative systematic error is given in Equation (56):

\[ \xi_r = \frac{v_{\text{est}}}{v_0} - 1 = -\frac{kt_1 + kt_2}{2} \approx -\frac{\xi_1 + \xi_2}{2} \]  

(56)

where \( \xi_r \) is the relative extent of reaction, given by Equation (57):

\[ \xi_r = \frac{a_0 - a}{a_0} = 1 - e^{-kt} \]  

(57)

and \( \xi_r \approx kt \) for values of time small enough. Thus the relative systematic error will coincide with the average relative extent of reaction of the experimental points used to evaluate the initial rate.

Commonly, the signal values are not reliable close to the origin, due to the mixing effect and the induction period; therefore, a better approach is to fit the initial measured pairs \((t, S)\) to an orthogonal polynomial series \(\sum a_i t^i\) from which the smoothed derivative is calculated and extrapolated at zero time.

The initial rate measurements are faster than those based on integral methods since the reaction is not required to reach completion, and can be applied to very slow reactions. Another advantage is that complications from side reactions are avoided. However, the mechanistic conclusions obtained about the reaction orders are only valid for the beginning of the reaction since these parameters can change, especially for reactions with complicated rate laws. Therefore, it is always highly recommended to complete the study with the aid of an integral method.

2.5.4.3 Use of Integrated Equations

The use of the integrated rate equation is, maybe, the most popular technique to determine the rate constant. This method is acceptable once the reaction orders are known, because the integrated rate equation depends on the \( p \) and \( q \) values. When reaction orders are unknown, or if it is suspected that they can take fractional values, the methods given above are preferable, since in this case, the use of the integrated equation should be based on a trial and error method, and it is really difficult to distinguish between two close fractional values. Table 2 shows integrated equations\(^{(a)}\) found frequently in the experimental work.

2.5.4.4 Mixed Simple–Complicated Equations

Very often, it is found that reactions with complicated rate equations present a simple form for one of the reactants and a complicated form for the other. In this case, the rate law could be written as shown in Equation (58):

\[ -\frac{da}{dt} = f(r) a^p \]  

(58)

where it was supposed that the kinetic behavior of reactant A was simple while reactant R presented a complicated form. In this situation, the kinetic study is carried out by running a reaction series where the reactant R is in excess\(^{(7)}\). Under these experimental conditions, where less than 1–10% of R is consumed, the rate law takes the simple form shown in Equation (59):

\[ -\frac{da}{dt} = f(r_0) a^p \approx k_{\text{app}} a^p \]  

(59)

Now, the techniques seen in the above sections enable us to find the reaction order with respect to the limiting reactant, but the dependence of the rate law on \( r \) must be deduced from a plot of \( k_{\text{app}} \) versus the initial concentration \( r_0 \).

A typical example is the dependence of most enzymatic reactions on pH; the rate presents a simple dependence on the substrate concentration, but the dependence on the proton concentration frequently exhibits a sigmoidal or bell-shaped curve explained by the acid–base equilibria established among the enzyme, activated complex, and substrate with protons.

There is not a systematic procedure to deduce the mechanism of a reaction from its \( k_{\text{app}}(r_0) \) curve. Generally, several mechanisms are proposed based on additional information such as the structure of the products or the reactivity of the functional groups involved. Once the reaction mechanism has been derived, it is simplified on the basis of the steady state or the presence of pre-equilibria, and a rate law is obtained from which it is possible to get a theoretical equation for \( k_{\text{app}}(r_0) \), which is compared to the experimental data in order to calculate the more relevant kinetic parameters.

The procedure does not ensure the validity of a mechanism whose curve \( k_{\text{app}}(r_0) \) fits correctly the experimental one, but permits us to reject all mechanisms from which it is not possible to deduce a reasonable shape for \( k_{\text{app}}(r_0) \).

2.6 Treatment of Complex Mechanism

Complicated rate laws arise from complex reactions that need more than one differential equation and two or more extents of reaction to be described. For instance, the reaction used for the determination of oxygen peroxide with dichromate in acidic media\(^{(8)}\) proceeds in two steps, the formation of the blue peroxychromic acid and its decomposition to yield aqueous Cr(III). The reaction mechanism consists of several elementary steps, and even

$\alpha$, Concentration of limiting reactant A; $a_0$, $r_0$, initial concentration of species A and R; $r_\infty$, final concentration of species R. $\alpha = a/a_0, c = r_\infty A_A/\alpha(\alpha R)$.

applying the pre-equilibrium and the steady-state simplifications, it needs two reaction extent variables, one for the formation of the peroxychromic acid and the other for its decomposition, to describe all concentration variations.

Methods described in section 2.5 cannot be used for dealing with complex reactions with complicated rate laws, since the $\alpha$ variable relating the physical response and concentrations was deduced on the basis that a unique extent of reaction was needed.

The general data treatment of complex reactions, including those with complicated behavior, is carried out by developing a system of o.d.e.s from the reaction mechanism. The resolution of this system yields the theoretical concentration values, from which the monitored physical property can be estimated as a function of time. The comparison of estimated and experimental signal values by a regression method allows the model validity to be checked.

In section 3.3.2, several regression methods will be studied, but the next sections are devoted to describing methods capable of calculating the concentrations at any time from any reaction mechanism. Complex mechanisms can be conveniently divided into first-order mechanisms (first-order networks) and general mechanisms due to the different mathematical techniques that can be used to solve the o.d.e. system associated with first-order networks.

2.6.1 First-order Networks

A first-order network arises from reaction mechanisms made up entirely of first-order elementary steps. Typical
experiments leading to first-order complex mechanisms are those conducted under pseudo-first-order conditions, or those based on perturbation methods. The general o.d.e. system associated with these models is linear and takes the general form shown in Equation (60):

$$\frac{dc}{dt} = Ac$$

where $c$ is a vector containing the species concentration, $t$ is the reaction time, and $A$ is a square $(N \times N)$ matrix, the elements of which are shown in Equation (61):

$$a_{ij} = k_{ji}, \quad a_{ii} = -\sum_{j=1}^{N} k_{ij}$$

where $N$ is the number of species in the reaction system, and $k_{ij}$ the rate coefficient for the reaction that converts $i$ species into $j$ species (many $k_{ij}$ can have a zero value).

### 2.6.1.1 Integration of First-order Networks

The first-order mechanisms are classified as reversible or irreversible. For the reversible mechanisms, the analytical solution is given by Equation (62):

$$c_i(t) = \sum_{j=1}^{N} u_{ij} g_j e^{\lambda_j t}$$

where $c_i$ is the $i$th species concentration at time $t$, $u_{ij}$ the elements of matrix $U$ that contain the eigenvectors of matrix $A$, $\lambda_j$ being its $j$th eigenvalue, and $g_j$ is a constant related to the initial conditions of the problem.

The reaction matrix $A$ derived from a reversible network can be converted into a real symmetrical matrix, $A'$, by applying the similarity transformation shown in Equation (63):

$$A' = D^{-1}AD$$

where $D$ is a diagonal matrix containing the square root of the equilibrium concentrations of the species. The eigenvectors and eigenvalues of a symmetrical real matrix are always real and can be obtained by the simpler Jacobi’s diagonalization method.$^{(4)}$ From the matrix $U'$, containing the eigenvectors of matrix $A'$, the matrix $U$ is calculated as shown in Equation (64):

$$U = DU'$$

The $g$ vector ensures the compatibility of the general solution with the boundary conditions of the problem, and is calculated from the initial species concentration and the eigenvectors of $A$. At zero time, Equation (62) gives Equation (65):

$$c_i(0) = \sum_{j=1}^{N} u_{ij} g_j \rightarrow c(0) = Ug \rightarrow g = U^{-1}c(0)$$

This algorithm is faster than numerical methods and is not affected by the stiff nature of the kinetic system. Another advantage is that the calculation time is not affected severely by the number of experimental points.

The above method cannot be applied to an irreversible first-order mechanism because the reaction matrix $A$, derived from an irreversible network, cannot be transformed into a real symmetrical matrix and it could have an incomplete set of eigenvalues. This leads to the reduction of exponential terms in Equation (36), and to the inclusion of polynomial terms, as illustrated in Table 3 for the consecutive mechanism when $k_1 = k_2$. Thus, for irreversible networks, the general solution for species concentration is given by Equation (66):

$$c_i(t) = \sum_{j=1}^{N} u_{ij} \frac{m_j!}{(m_j - 1)!} e^{\lambda_j t}$$

where $m_j$ is the multiplicity of the $j$th eigenvalue of $A$.

Now, the Laplace transform technique$^{(9)}$ can be used to integrate irreversible first-order networks.$^{(10)}$

This procedure is expected to work faster than numerical methods and is hardly dependent on the number of experimental points. The technique, however, needs more calculus time than the eigenvector method used for reversible networks, since the $U$ matrix is calculated by solving $N$ linear equation systems. This fact makes the procedure more size-dependent than the eigenvector method.

| Table 3 Integrated rate laws for common first-order mechanisms$^a$ |
|-----------------|-----------------|-----------------|
| **Equilibrium reactions** |
| $A \xleftarrow{k_1} B \xrightarrow{k_1} C$ | $a = a_0 \left\{1 - \frac{k_1}{k_1 + k_{-1}} [1 - e^{-k_{1+1}t}]\right\}$ |
| | $b = a_0 \frac{k_1}{k_1 + k_{-1}} [1 - e^{-k_{1+1}t}]$ |
| **Consecutive reactions** |
| $A \xrightarrow{k_1} B \xrightarrow{k_2} C$ | $a = a_0 e^{-kt}$ |
| | $b = a_0 k_1 e^{-k_2 t}$ |
| | $c = a_0 - a - b$ |
| **Parallel reactions** |
| $A \xleftarrow{k_1} B \xrightarrow{k_2} C$ | $a = a_0 e^{-k_{1+2}t}$ |
| | $b = a_0 \frac{k_1}{k_1 + k_2} [1 - e^{-k_{1+2}t}]$ |
| | $c = a_0 \frac{k_2}{k_1 + k_2} [1 - e^{-k_{1+2}t}]$ |

$^a$ Initial concentrations for $A, B, C$ were $a_0, 0, 0$ respectively.
2.6.2 Data Treatment of a General Analysis in Kinetics

When reactions higher than first-order appear in the reaction mechanism, the o.d.e. shown in Equation (67) describes the general reaction system:

\[
\frac{dc_n}{dt} = \sum_{i=1}^{R} v_{in} k_i^n \gamma_i c_j^n
\]  

(67)

where \( N \) is the number of species in the system, \( R \) the number of reactions, \( k_i \) is the rate coefficient associated with the \( i \)th reaction, \( v_{in} \) the stoichiometric coefficient of the \( n \)th species in the \( i \)th reaction, and \( \gamma_i \) the reaction order of the \( i \)th species in the \( i \)th reaction. In order to generalize the problem, the reaction orders, \( \gamma_i \), can take any real number. However, if the reaction mechanism is used, only elementary steps are involved and the orders will be equal to the stoichiometric coefficients.

Frequently, the number of reactions is lower than the number of species, and the number of differential equations can be reduced by carrying out a change of variable. The new variables will be the extents of reaction, \( \xi \), which are linearly related to the concentrations as shown in Equation (68):

\[
c_n = c_{n,0} + \sum_{j=1}^{R} v_{nj} \xi_j
\]  

(68)

where \( c_{n,0} \) is the initial concentration of the \( n \) species. The new o.d.e. is described by Equation (69):

\[
\frac{d\xi_j}{dt} = k_i^n c_{n,0} + \sum_{j=1}^{R} v_{nj} \xi_j
\]  

(69)

Now the mathematical model is a system of \( R \) differential equations instead of \( N \).

2.6.3 Numerical Integration of Kinetic Systems

The ordinary methods used to solve numerically o.d.e. systems are based on the calculation of a solution at time \( t + h \) (where \( h \) is the integration step) from a solution known at time \( t \), an integration scheme that is known as explicit. The value of \( h \) cannot be taken arbitrarily because it controls the accuracy at which the new solution is calculated and, thus, the stability of the integration procedure; small steps waste calculation time and increase the round-off error, and unreasonably large steps result in a diverging integration.

Several explicit integration methods can be applied to kinetic differential equation systems, such as the Runge–Kutta type methods or the predictor–corrector methods. However, step size control is cumbersome, and high accuracy is difficult to obtain. A better approach for kinetic problems is to apply the explicit Taylor method, which allows a direct and complete control of the step size.

The Taylor method is based on developing the solution as a polynomial series. It is clear that the solution at times \( t \) and \( t + h \) are related by the Taylor formula shown in Equation (70):

\[
c^{(0)}(t + h) = c^{(0)}(t) + \sum_{k=1}^{Q} \frac{h^k}{k!} c^{(k)}(t)
\]  

(70)

where \( c \) is a vector containing the concentrations, and the superscripts in parentheses refer to the derivative order. It is obvious that this expression can be applied if the \( Q \) first derivatives are known. This task can be done as follows. The first derivative of the concentration of the \( n \)th species at time \( t \) is given by Equation (71):

\[
c_n^{(1)}(t) = \sum_{i=1}^{R} v_{in} k_i^n \gamma_i c_j^n = \sum_{i=1}^{R} v_{in} \Phi_i(t)
\]  

(71)

Thus, deriving the above expression \((k + 1)\) times yields Equation (72):

\[
c_n^{(k+1)}(t) = \sum_{i=1}^{R} v_{in} \Phi_i^{(k+1)}
\]  

(72)

where the \((k + 1)\)th derivative of \( \Phi_i \) can be calculated with the algorithm in Equation (73), derived from its own definition after applying the Leibniz rule:

\[
\Phi_i^{(k+1)} = \sum_{j=1}^{k} \left( \binom{k}{j} T_i^{(j)} \Phi_i^{(k+1-j)} \right)
\]  

(73)

where \( T_i^{(j)} \) is obtained from Equations (74) and (75):

\[
T_i^{(j)} = \sum_{n=1}^{N} \gamma_n f_i^{(j)}
\]  

(74)

\[
f_i^{(j)} = \frac{\frac{c_i^{(j)}}{c_i^{(0)}} - 1}{\sum_{i=1}^{n-1} \left( k - 1 \right) f_i^{(j-1)}}
\]  

(75)

The recurrent algorithm starts with the values shown in Equation (76):

\[
f_i^{(1)} = \frac{c_i^{(1)}}{c_i^{(0)}}, \quad T_i^{(1)} = \sum_{n=1}^{N} \gamma_n f_i^{(1)}
\]  

(76)

The Taylor method allows the integration error to be controlled in a straightforward way. Equation (70) indicates that the error committed in the calculation of \( n \)th concentration at time \( t + h_n \), is given by the \( Q \) + 1 term in the Taylor series shown in Equation (77):

\[
O_n(h_n) = \frac{h^{Q+1}}{(Q + 1)!} c^{(Q+1)}
\]  

(77)
It is desirable that the relative error is below a given value:

\[ O_n(h_n) \leq \varepsilon^{(0)} \quad (78) \]

The combination of Equations (77) and (78) affords the desired result:

\[ h_n \leq \left\{ \frac{\varepsilon}{(Q + 1)!} \frac{c^{(0)}_n}{c^{(Q+1)}_n} \right\}^{1/(Q+1)} \quad (79) \]

Finally, as each species requires its own step, convergence is ensured by taking the smallest integration step as given in Equation (80):

\[ h = \min(h_n) \quad (80) \]

This method has been shown to be better than other explicit methods for accurately integrating nonstiff and moderately stiff kinetic models,\(^{11}\) and it can be modified\(^{13}\) to cope with stiff systems.

The stiffness of a kinetic problem arises from mechanisms where steps coexist with very different rates. This drastically slows down the numerical integration process, because the integration step depends inversely on the rate constants. Thus, the existence of fast processes implies a small step slowing down the whole integration procedure. Stiffness is a serious problem because the nonlinear least-squares (NLS) minimization routines could need the o.d.e. system to be integrated several thousands of times, and during the minimization process there is a high probability of finding a stiff area. If such an event occurs and a nonstiff integration method is being used, the minimization procedure will suddenly slow down, taking much more time to complete a minimization cycle.

For first-order o.d.e. systems, stiffness can be solved by a change of variable that can decouple the o.d.e. systems. Then each o.d.e. can be integrated separately. This is the strategy followed by the methods shown in section 2.6.1.1. However, the situation is rather more complicated for nonlinear o.d.e. systems where this procedure is not operative.

It has been well established that the integration routines able to solve stiff problems should be based on implicit or semi-implicit numerical methods.\(^{14}\) That means that the knowledge of the solution of the o.d.e. at time \(t + h\) is obtained by solving an algebraic equation system, whose unknown variables are, precisely, the o.d.e. solutions. The procedure presents obvious advantages for stiff systems that can be solved in a short space of time, but implicit methods are much more complex and have disadvantages when they are applied to nonstiff problems due to the time employed in solving the algebraic system. In such cases, a waste of calculation time and a relatively poor accuracy in the numerical solution could be observed. There are several types of algorithms available to solve stiff o.d.e. systems,\(^{14}\) including the Bader–Deuflhard algorithm and the Gear method. Also an implicit Taylor method can be developed to obtain precise solutions for nonlinear stiff systems.

### 3 ERROR ANALYSIS IN CHEMICAL KINETIC METHODS

The study of sources of error and their effects on results is an essential part of data treatment. Errors can be divided into random and systematic. In this section, random errors are those inherent to the measurement process, affecting the results in an unpredictable way, and they can be averaged away using enough data. Random errors can be quantified by the standard deviation of the results.

However, systematic errors arise mainly from uncontrolled changes in the factors that modify the reaction rate, and from the simplifications made in the mathematical models. This kind of error will not average away using any amount of data. Sources of systematic errors must be carefully controlled because it is difficult to detect this kind of error.

#### 3.1 Factors Influencing the Reaction Rate

The reaction rate, and therefore most of the kinetic methods, are strongly dependent on several factors such as temperature, reactant concentration, ionic strength, and solvent nature. The reaction rate can be adjusted to a practical range controlling these factors. However, variations out of control can lead to important systematic errors.

The Arrhenius equation shown in Equation (81) is an empirical relationship describing the dependence of the rate constant, \(k\), on the absolute temperature, \(T\):

\[ k = A e^{-\frac{E_a}{RT}} \quad (81) \]

where \(E_a\) is the activation energy, with dimensions of energy per mole, \(A\) is the pre-exponential factor having the units of \(k\), and \(R\) is the universal gas constant (8.31 J K\(^{-1}\) mol\(^{-1}\)).

For many homogeneous reactions, the activation energy ranges between 50 and 100 kJ mol\(^{-1}\), and thus, the rate constant increases by a factor of 2–4 per 10 °C rise in room temperature. For instance, a temperature variation of 0.1 °C produces a 1% change in the rate constant at room temperature for a reaction having an activation energy of 75 kJ mol\(^{-1}\).

The reactant concentration has a proportional effect on the reaction rate. For a pseudo-first-order reaction, the kinetic constant is directly proportional to the reagent concentration as shown in Equation (82):
The reaction rate of this system is given by Equation (84):

\[ K = k_1[R] \]  

(82)

Therefore, the concentration errors are correlated with those of the reaction rate. The simplest treatment to quantify the influence of ionic strength on the reaction rate is based on the transition-state theory. This theory considers that a fast pre-equilibrium step is established among reactants and the activated complex as shown in Equation (83):

\[ A + R \rightleftharpoons AR^* \longrightarrow P \]  

(83)

The reaction rate of this system is given by Equation (84):

\[ v = k[AR^*] = kK^{\gamma A/\gamma R}[A][R] \]  

(84)

where \( K^* \) is the thermodynamic equilibrium constant for the formation of the activated complex, and \( \gamma_A, \gamma_R, \) and \( \gamma_{AR^*} \) the activity coefficients of the species. The activity coefficient can be related to the ionic strength, \( I \), by the extended Debye–Hückel equation:

\[ \log \gamma_i = -\frac{AZ_i^2\sqrt{T}}{1 + a_iB\sqrt{T}} + b_iI \]  

(85)

where \( Z_i \) is the charge of the \( i \)th species, and \( b_i \) becomes significant for neutral species or high ionic strengths. Considering that the product \( a_iB \) is usually taken as unity, and that \( Z_{AR^*} = Z_A + Z_R \), substitution of the activity coefficients in Equation (84) by the expression in Equation (85) leads to Equation (86):

\[ \log k = \log k_0 + \frac{2AZ_AZ_R\sqrt{T}}{1 + \sqrt{T}} + bI \]  

(86)

where \( k_0 \) is the rate constant at zero ionic strength. This expression indicates that changes in the ionic strength scarcely affect the rate of reactions taking place between neutral species, or an ion and a neutral molecule, since the product \( Z_AZ_R \) cancels out and \( b \) is usually small. In addition, the rate of a second-order reaction between equally charged ions should increase as the ionic strength increases, whereas the rate of a reaction between oppositely charged ions should decrease. For instance, an increase of ionic strength from 0.01 to 0.011 produces a 1% change in the rate constant for a reaction taking place between monocharged ions. The effect is considerably higher for low ionic strengths; thus, a change of 7% is observed when the ionic strength increases from 0 to 0.001.

The rate of a chemical reaction can be modified by the nature of the solvent. In spite of its complexity, Equation (87) shows that a linear variation in \( \ln(k) \) with the inverse of the dielectric constant of the solvent, \( 1/\varepsilon \), is observed with reasonable accuracy:\(^{(15)}\)

\[ \ln k = \ln k_0 + \frac{1}{\varepsilon} \]  

(87)

where \( k_0 \) is the rate constant in a medium of infinite \( \varepsilon \), and \( m \) a constant depending on temperature, charge, ionic radius, and the dipole moments of reactants and activated complex. Equation (87) suggests that an increase in solvent polarity favors those reactions where an activated polar complex is formed, and slows down those reactions occurring through a nonpolar activated complex. Hence, the solvent has a drastic influence on the rate constant. For instance, the reaction rate of triethylamine with ethyl iodide suffers a 4200% increase when changing from benzene to acetonitrile.\(^{(1)}\)

Finally, it could be of interest to compare equilibrium and rate measurements. According to the relationship in Equation (88) relating the equilibrium constant to the forward and reverse rate constants:

\[ K = \frac{k_f}{k_i} \]  

(88)

the effect of the experimental conditions might be lower on the equilibrium constant than on the rate constants due to the compensation of errors in Equation (88). Therefore, in order to obtain good results with kinetic-based methods, the experimental conditions must be controlled more carefully than is usual in the equilibrium-based methods.

### 3.2 Methods Based on First-order Reactions for the Determination of One Species

From a practical analytical viewpoint, most kinetic methods for the determination of a single species are carried out in pseudo-first-order conditions. Table 4 shows the most frequently used experimental conditions in uncatalyzed, catalyzed, and enzymatic methods in order to assure pseudo-first-order kinetics. Depending on the original mechanism, the pseudo-first-order rate constant will be a function of several experimental factors, such as the reagent concentration. The rate law in Equation (89) summarizes the different cases in a general form:

\[ v = \frac{d[A]}{dt} = -(k_c[C]_0 + k_u[R]_0)[A] = -k[A] \]  

(89)

where \( k_c \) and \( k_u \) are rate constants for the catalyzed and uncatalyzed reactions, respectively. On integration Equation (89) leads to Equation (90):

\[ [A] = [A]_0 e^{-kt} = [A]_0 e^{-k_c[C]_0t + k_u[R]_0t} \]  

(90)

Now, after taking into account the linear dependency of the response upon concentration given by Equation (31)
for first-order reactions, we can write Equation (91):

\[ S = S_\infty - s[A_0]_0 e^{-kt} = S_0 + s[A_0]_0(1 - e^{-kt}) \]  

where \( s \) is a linear combination of the proportionality constants of the different species with signal. For instance, \( s = s_p - s_A - s_R \) for the reaction \( A + R \rightarrow P \).

Data treatment can be done by applying several strategies.\(^{(16)}\) The different data used by each treatment appear in the kinetic profile shown in Figure 3. In the fixed time method the signal values \( S_1 \) and \( S_2 \) are measured at constant times \( t_1 \) and \( t_2 \). On the contrary, in the variable time method the time values are measured, whereas the signal values remain constant. In the initial rate method, initial rate, \( v_0 \), is measured as the slope, near the origin, of the kinetic curve. Finally, the predictive kinetic (PK) method\(^{(17)}\) is based on the extrapolation of a fitted kinetic profile to the predicted final signal, \( S_\infty \).

### 3.2.1 Implicit Systematic Errors of the Data Treatment

The fixed and variable time methods are based on the change of the signal during a time interval \( \Delta t \). For a first-order reaction we obtain Equation (92):

\[ \frac{\Delta S}{\Delta t} = s[A_0]_0 \frac{e^{-kt_1} - e^{-kt_2}}{t_2 - t_1} = s[A_0]_0 e^{-kt_1} \frac{1 - e^{-k\Delta t}}{t_2 - t_1} \]  

where \( t_2 = t_1 + \Delta t \). The expansion of the exponential function in a Maclaurin series, Equation (53), yields Equation (93):

\[ \frac{\Delta S}{\Delta t} = ks[A_0]_0 e^{-kt_1} \sum_{i=1}^{\infty} \frac{(-k\Delta t)^{i-1}}{i!} = k[A_0]_0 \Omega \]  

where \( \Omega \) is a calibration factor depending on the products \( k_{t_1} \) and \( k_{t_2} \).

The determination process can be divided into the calibration and the sample measurement steps. The calibration step allows us to calculate the value of \( \Omega \) from standards of known concentration. This value will be used in the determination of analyte concentration in the sample. The result will fit to the real concentration, when the factor \( \Omega \) remains constant between the calibration and the sample measurements. Taking \( t_1 \) the closest to zero reduces the error and increases the sensitivity. On the other hand, the more similar the calibration and sample concentrations, the closer the \( \Omega \) values. The data treatment also has an important effect. When the initial concentration of the limiting reagent, \( A \), is determined, the rate constant remains invariable between the calibration procedure and the sample determination. Thus, \( \Omega \) will keep constant for the fixed time method, but not for the variable time method, and a systematic error will be produced. This situation is also applicable to

**Figure 3** Signal–time profile for a first-order reaction. Some data treatment used in kinetic methods are shown.
the determination of substrate concentration in enzymecatalyzed reactions which exhibit a similar pseudo-first-order kinetic behavior, as shown in Table 4.

When a catalyst is determined, the rate constant will change between the standards and the sample, and thus Ω will vary for the fixed time method, introducing a systematic error. However, the product kt will remain constant for the variable time method, since this quantity is related to the signal as Equation (94) shows:

$$kt = -\ln \left( \frac{S_\infty - S}{S_\infty - S_0} \right)$$

(94)

where $S$, $S_\infty$, and $S_0$ are constants, making Ω invariable. The same situation is found for uncatalyzed reactions when the species to be determined is the reagent in excess, R, but now a small systematic error is committed when R affects the signal value.

Another approach, shown in Equation (95), takes the logarithm of the signal ratio:

$$\frac{1}{\Delta t} \ln \frac{S_\infty - S_1}{S_\infty - S_2} = k_c [C]_0 + k_u [R]_0$$

(95)

In this case, the fixed time method can be used without systematic error when $S_\infty$ is known. When it is unknown, and the logarithm of the signal ratio is used, Equation (96) is obtained:

$$\ln \frac{S_1}{S_2} = k \Delta t + \ln \frac{S_\infty e^{k_1 t} - S_\infty + S_0}{S_\infty e^{k_1 t} - S_\infty + S_0}$$

(96)

Now, a systematic error is expected, but smaller than that obtained using ΔS, because of the quotient error compensation in Equation (96).

Figure 4 shows the performance of the fixed and variable time methods. According to the above conclusions, the variable time method will give the best results when a catalyst is determined, whereas the fixed time method will be superior for the determination of the limiting reagent for uncatalyzed reactions.

Ingle and Crouch\(^{18}\) have also shown that the variable time methodology has a wider range of catalyst concentration amenable to determination, in spite of the difficulty involved in developing a general treatment, owing to the large variety of possible mechanisms encountered. Furthermore, the authors concluded, on the basis of a study of the theoretical and experimental factors influencing the accuracy of reaction rate measurements, that the variable time approach is superior in most cases where nonlinear response curves are obtained.

A different approach can be applied by fitting the whole kinetic curve to the integrated equation to obtain $k$ and $[A]_0$. When the rate constant is the analytical parameter, the method of tangents can be used. In this method, the linear fit of Equation (35) yields, as the slope, the rate constant, which is linearly related to the catalyst concentration. When the final signal is unknown, the Guggenheim or KMS methods should be used as illustrated in section 2.5.2.1. Finally, since the method of tangents performs more measurements to obtain the rate constant, its application is expected to result in better precision than the variable or fixed time methods. However, the method of tangents is highly affected by model nonlinearities and fails when the kinetics is complex, and the integration of the rate equations is difficult or impossible.

When the initial concentration of the limiting reagent is to be determined, the PK method can be applied. The method is based on the extrapolation of a fitted kinetic profile to predict the signal at the end of the reaction. The advantage of this approach is the bypassing of errors due to experimental changes in $k$ that go with changes in temperature, reagent concentration, or ionic strength. Two approaches can be used, the consecutive linear determination of $k$ and $[A]_0$, or the simultaneous nonlinear determination of $k$, $[A]_0$, and $S_0$, based on Equation (91). Baeza-Baeza et al.\(^{19}\) evaluated several methods for the determination of an analyte following pseudo-first-order kinetics, and observed that the PK method gave the best results, specially when the average
rate constant of all kinetic runs is used instead of the individual ones. This fact indicates that random errors in the constant have an important effect on the extrapolated final signal; this effect decreases when the extent of the reaction increases, that is, as the extrapolation risk decreases.

The rate methods are differential approaches based on the relation of the reaction rate with concentration as shown in Equation (97):

\[ v = \frac{dS}{dt} = s k[A]_0 e^{-kt} \] (97)

The initial rate method is based on the measurement of the slope of the kinetic curve at initial times, as is shown in Equation (54). As stated by Equation (56), the smallest possible error is obtained when the measurement is made as close to the origin as the mixing time and induction period permit. It is recommended that no more than 2% reactant conversion be allowed to occur. In addition, a reduction in the systematic error can be done if the initial rate is obtained by fitting the initial values of the signal to an orthogonal polynomial series.

On the other hand, an error compensation occurs between calibration and determination in the global process. Therefore, bearing in mind that Equation (54) is a simplified version of Equation (93), similar conclusions to those previously outlined will be obtained when the model follows first-order kinetics near the origin. However, for catalyzed reactions, including enzymatic ones, the initial kinetics could not follow a first-order model owing to the induction period necessary to reach the stationary state. The advantages generally attributed to initial rate measurements include the minimal complications from side reactions, and the increased sensitivity over other rate measurements, since the exponential value in Equation (97) is unity when \( t = 0 \).

Finally, it should be realized that the success of the initial rate method depends greatly on the availability of sufficiently sensitive and reproducible monitoring of small signal changes.

A special case is found in the determination of the enzyme activity because, as shown in Table 4, the reaction follows a zero-order law under saturation conditions. In order to study the error of this treatment, an integration of the Michaelis–Menten equation must be done.\(^{20} \) A good approximation is to suppose that \([S] \equiv [S]_0 - [P]\) when \([S]_0 \gg [E]_0\); now, considering that the signal is produced by the product of the reaction, \( S = s p [P] \), the integrated equation has the form shown in Equation (98):

\[ S = s p k_2 [E]_0 t - s p K_m \ln \left( \frac{S_\infty}{S_\infty - S} \right) \] (98)

This expression allows signal and time variations to be related as shown in Equation (99):

\[ \frac{\Delta S}{\Delta t} = s p k_2 [E]_0 - s p K_m \frac{\ln[(S_\infty - S_1)/(S_\infty - S_2)]}{\Delta t} \] (99)

The final signal, \( S_\infty \), is expected to be large compared to \( S_1 \) and \( S_2 \) due to the saturation conditions, and, thus, the logarithm can be expanded by means of a Taylor series to Equation (100):

\[ \ln \left( \frac{S_\infty - S_1}{S_\infty - S_2} \right) \approx \frac{S_2 - S_1}{S_\infty - S_2} = \frac{\Delta S}{S_\infty - S_2} \] (100)

leading to Equation (101):

\[ \frac{\Delta S}{\Delta t} = \frac{s p k_2 (S_\infty - S_2)}{S_\infty - S_2 + s p K_m} [E]_0 = m [E]_0 \] (101)

Thus, if the variable time method is applied, the slope, \( m \), will remain constant since \( S_2 \) has a constant value. On the other hand, \( S_2 \) varies in the fixed time method, and \( m \) is not constant, resulting in a systematic error. Figure 5 shows the application of both methods to the enzymatic activity determination by using an increasing time interval. The variable time method gives better results when the extent of the reaction is high enough to ensure the validity of the stationary state and the Michaelis–Menten equation. However, this hypothesis is not valid at the beginning of

![Figure 5](image-url) **Figure 5** Variation of the mean relative error of the data used with increasing extent of reaction in the determination of two enzyme concentrations (2.5 and 3.5 nM), applying the fixed time (○) and the variable time (●) approach. A calibration of five points (1, 2, 3, 4 and 5 nM) was used. The kinetic constants of the Michaelis–Menten mechanism were \( k_1 = 50 \), \( k_{-1} = 20 \), \( k_2 = 200 \) and \([S]_0 = 1 \mu M\).
the reaction. The fixed-time method improves itself as the time interval decreases, approaching the data treatment of the initial rate method, whereas the variable time method gives worse and worse results because it evaluates the initial rate at different times. It must be realized that the reaction rate increases almost linearly with time at the beginning of reaction, as shown in Equation (102):

\[
v(t \to 0) = k_2[E][S]_0 \to 0 \cong \frac{k_2k_1}{k_{-1} + k_2} \left[ 1 - e^{-(k_{-1} + k_2)t} \right][S][E]_0
\]

\[
\cong k_2k_1[S][E]_0
\]  

(102)

where \([E][S]_0 \to 0\) has been obtained by integration of Equation (10) supposing that \(S\) and \(E\) concentrations remain constant and equal to their initial values. Thus, the fixed time method will yield better results near \(t = 0\).

3.2.2 Propagation of Systematic Errors

The study of the sources of systematic errors can lead to an optimum experimental design minimizing the error propagation. Systematic errors can arise from changes in the rate constant between calibration and sample determination, owing to variations in the factors that affect the reaction rate.

When the fixed-time method is applied to an uncatalyzed reaction, the linear calibration model will be as shown in Equation (103):

\[
\Delta S = m[A]_0 + n
\]  

(103)

where \(m\) and \(n\) are the calibration parameters. A systematic error in the rate constant, \(\varepsilon_k\), will cause the systematic error given in Equation (104) for the initial concentration of the analyte:

\[
\varepsilon_A = \frac{\partial \Delta S}{\partial k} \frac{\varepsilon_k}{m} = s[A]_0 \frac{\varepsilon_k}{m} = [A]_0 \frac{\varepsilon_k}{k}
\]  

(104)

The error will be zero if the times are chosen according to Equation (105):

\[
t_1e^{-kt} = t_2e^{-kt}
\]  

(105)

The function \(te^{-kt}\) has a bell shape with a maximum at \(t = 1/k\). As time moves away from this value, the function decreases. As a consequence, the optimal approach consists of choosing the biggest \(t_2\) possible to lower the \(te^{-kt}\) function, and resolving Equation (105) for \(t_1\).

When a catalyzed reaction is treated by the variable time approach, the analytical function is \(1/\Delta t\), and the error is given by Equation (106):

\[
\varepsilon_C = \frac{\partial (1/\Delta t)}{\partial \varepsilon_k} \frac{\varepsilon_k}{m} = \frac{[C]_0}{\ln([S]_\infty - S_1)/([S]_\infty - S_2)]} \frac{\varepsilon_k}{m}
\]  

(106)

In this case, the error decreases when \(\Delta S\) increases, since the logarithm also increases.

Regarding the initial rate method, taking into account that in this case \(m = sk\), its application leads to a constant error as shown in Equation (107):

\[
\varepsilon_A = \frac{\partial (\varepsilon_k)}{\partial k} \frac{\varepsilon_k}{m} = s[A]_0 \frac{\varepsilon_k}{m} = [A]_0 \frac{\varepsilon_k}{k}
\]  

(107)

Thus, the relative error in \(k\) propagates irremovable to the relative concentration error. Holler et al.\(^{(21)}\) studied the propagation of errors in the instantaneous rate measurement. From Equation (97) is obtained Equation (108):

\[
\varepsilon_A = \frac{\partial (\varepsilon_k)}{\partial k} \frac{\varepsilon_k}{m} = s[A]_0(1 - kt)e^{-kt\varepsilon_k} \frac{m}{k} = [A]_0(1 - kt) \frac{\varepsilon_k}{k}
\]  

(108)

This expression shows that the reaction rate values are independent of changes in parameters affecting the value of the rate coefficient at a time equal to \(1/k\). Besides, when the initial rate is measured, time equals zero and the propagated error is one of the largest.

The precision in the determination of an analyte by using the PK extrapolation method depends significantly on the extent of the reaction concerned. Let us suppose that an extrapolation is carried out using only one data point as in Equation (109):

\[
[A]_0 = \frac{S - S_t}{1 - e^{-kt}}
\]  

(109)

From Equation (109) it is clear that the error in \([A]_0\) due to an error committed in \(k\) is given by Equation (110):

\[
\varepsilon_A = \frac{\partial [A]_0}{\partial k} \varepsilon_k = -\frac{[A]_0te^{-kt}\varepsilon_k}{1 - e^{-kt}}
\]  

(110)

Now, taking into account that the extent of reaction is \(\xi = 1 - e^{-kt}\), the relative error in \([A]_0\) will be as shown in Equation (111):

\[
\varepsilon_{\xi} = \frac{1 - \xi}{\xi} \varepsilon_{\xi}
\]  

(111)

Carr\(^{(22)}\) studied this effect showing that the relative precision improves monotonically with increasing \(\xi\), and that the relative uncertainty in \([A]_0\) tends to the relative uncertainty in \(k\) at small values of \(\xi\); finally, when the reaction approaches completion (\(\xi \to 1\)), the uncertainty in the measurement of \(k\) causes no appreciable systematic error in the estimated concentration.

Another kind of systematic error arises from the presence of an interferent species, \(B\), in the sample. In this case, the variation of the signal in the sample for an uncatalyzed reaction is given by Equation (112):

\[
\Delta S = S_A[A]_0(e^{-ka_{t1}} - e^{-ka_{t2}}) + S_B[B]_0(e^{-ka_{t1}} - e^{-ka_{t2}})
\]  

(112)
The relative error in the determination of $A$, supposing the calibration standards are free of $B$, and applying the fixed time method, is given by Equation (113):

$$
\varepsilon_{ra} = \frac{s_B \left[B\right]_0 e^{-k_B t} - e^{-k_B t}}{s_A \left[A\right]_0 e^{-k_B t} - e^{-k_B t}} \quad (113)
$$

This expression shows that the error increases when $k_B$ increases and decreases when $t_1$ and $\Delta t$ decrease. Obviously, error decreases with $s_B$ and $[B]_0$.

The error of the variable time method for a catalyzed reaction with interference from another catalyst is given by Equation (114):

$$
\varepsilon_{rc} = \frac{[B]_0 k_C}{[C]_0 k_B} \quad (114)
$$

where the error depends only on the reaction rates and the initial concentration ratio. If the rate method has been used, the error will be as shown in Equation (115):

$$
\varepsilon_{ra} = \frac{s_B k_B [B]_0 e^{-k_B t}}{s_A k_S [A]_0 e^{-k_S t}} \quad (115)
$$

which is a minimum at $t = 0$, that is, for the initial rate method.

### 3.2.3 Propagation of Random Errors

The error propagation theory must be applied to obtain the parameter uncertainty due to random errors. For small independent errors in the variables, the propagation error rule is given by Equation (116):

$$
\sigma_y^2 = \sum \left( \frac{\partial y}{\partial y_i} \right)^2 \sigma_i^2 \quad (116)
$$

When an uncatalyzed reaction is used to determine the concentration of a substance by applying the fixed time method with, for simplicity, a unique calibration point, the result is given by Equation (117):

$$
[A]_{sm} = \frac{\Delta S_{sm}}{\Delta S_{cl}} \quad (117)
$$

where the subscript “sm” refers to the sample and “cl” to the calibration measurements. The mean square relative error of the concentration is given by Equation (118):

$$
\sigma_A^2 \left[ A \right]_{sm} = \frac{\sigma_{\Delta S_{sm}}^2}{\Delta S_{sm}^2} + \frac{\sigma_{\Delta S_{cl}}^2}{\Delta S_{cl}^2} \quad (118)
$$

This expression indicates that the relative square error in the evaluated concentration is the addition of the relative square error of the measured signal differences. The variance of the measured signal is given by Equation (119):

$$
\sigma_S^2 = \sigma^2 + \left( \frac{\Delta S_i}{\Delta t} \right)^2 \sigma_i^2 \quad (119)
$$

The signal is affected by its own uncertainty, $\sigma_i^2$, and by the uncertainty introduced for the lack of precision in time.

Now, supposing homocedastic data, Equation (120) is obtained:

$$
\frac{\sigma^2_{\Delta S}}{\Delta S^2} = \frac{\sigma^2_{\Delta S_{sm}} + \sigma^2_{\Delta S_{cl}}}{\Delta S_{sm}^2 + \Delta S_{cl}^2} \quad (120)
$$

The uncertainty decreases as $\Delta S$ increases, reaching a minimum when $S_2$ tends to $S_\infty$, and $S_1$ tends to the smallest signal value. On the other hand, the error increases as the reaction rate increases, owing to the higher uncertainty in the signal measurement produced by the time uncertainty.

When the variable time method is used to determine the concentration of catalyst $C$, the relative square error in the concentration is a function of the time interval measured as shown in Equation (121):

$$
\frac{\sigma_C^2}{[C]_{sm}} = \frac{\sigma^2_{\Delta S_{sm}} + \sigma^2_{\Delta S_{cl}}}{\Delta t_{sm}^2 + \Delta t_{cl}^2} \quad (121)
$$

and the relative square error of the time difference is given by Equation (122):

$$
\frac{\sigma^2_{\Delta t}}{\Delta t} = 2 \frac{\sigma^2_1}{2} + \frac{\sigma^2_2}{k^2 \Delta t^2} \frac{1}{(S_\infty - S_1)^2} + \frac{1}{(S_\infty - S_2)^2} \quad (122)
$$

In this case, the error depends on two opposite factors, the reduction of uncertainty when $\Delta t$ increases, and the lack of precision in the time measurement when $\Delta t$ tends to $S_\infty$. A graphical inspection of Equation (122) shows that precision increases as $S_\infty$ increases, $S_1$ decreases, and $S_2$ takes a value around 0.7 times $S_\infty$, at which Equation (122) has a minimum depending on $\sigma_1^2$, $\sigma_2^2$, and $k$ values.

### 3.3 Multicomponent Methods

Kinetic methods based on the different rates at which the components of a mixture react with a common reagent can be used to determine several analytes simultaneously. However, kinetic-based multicomponent determinations have found fewer applications than those devoted to the determination of only one species. This reflects the fact that conditions for determining more than one species simultaneously, and suitable multicomponent reactions, are difficult to find.

#### 3.3.1 Differential Methods

Several strategies have been employed in the simultaneous determination of two or more species. For two analytes, one of the most popular approaches has been the
logarithmic extrapolation method, because of its simplicity and its greater accuracy than other methods when the ratio of the rate constants is large. This method assumes that the signal is due to the slowest-reacting component, A, after reacting to completion the faster component, B. Equation (123) gives:

$$\ln(S_\infty - S) \approx -k_A t + \ln(s[A]_0)$$  \hspace{1cm} (123)$$

Thus, fitting the final data points, the concentration of the slower component can be evaluated from the difference between the final and the initial signal. Better component concentrations can be evaluated from the systematic error of the method depends on the extent of the reaction and the uncertainty in the final signal value. The above expression indicates that the analyte concentration can be obtained. The faster reaction increases and the extent of the slower reaction decreases. On the other hand, the systematic errors in the final signal can produce dramatic effects on the results. From Equation (123) and supposing that the value of $k_A$ is known, the error yields by the extrapolation from one data point, S, will be given by Equation (124):

$$\frac{\varepsilon_A}{[A]_0} = \frac{\varepsilon_{S_\infty}}{S_\infty - S}$$  \hspace{1cm} (124)$$

The overall process leads to an error that will be a function of a combination of terms like Equation (124) for all the points used. For this reason, to reduce the effect of the propagation of a systematic error in $S_\infty$, the points must be taken as near the origin as the reaction rates ratio permits.

Another widely used approach is the method of proportional equations, which involves the resolution of a system of simultaneous equations to obtain analyte concentrations. For two substances, Equation (125) relates the signal value to the analyte concentration:

$$S - S_0 = s_A[A]_0(1 - e^{-k_A t}) + s_B[B]_0(1 - e^{-k_B t})$$

$$= \Psi_A[A]_0 + \Psi_B[B]_0$$ \hspace{1cm} (125)$$

The above expression indicates that the analyte concentrations can be obtained by solving a system of linear equations when the signal is measured at two different times. This method does not require a prior knowledge of $S_\infty$, but the proportionality factors, $\Psi$, must be carefully evaluated at each time from pure solutions of A and B separately. Although the knowledge of $s$ and $k$ values should permit theoretical calculations of $\Psi$, the empirical evaluation is preferred to minimize the effect of experimental variables. The solutions of the system for two species is given by Equation (126):

$$[A]_0 = \frac{\Psi_{2B}S_1 - \Psi_{1B}S_2}{D} \hspace{1cm} [B]_0 = \frac{\Psi_{1A}S_2 - \Psi_{2A}S_1}{D}$$  \hspace{1cm} (126)$$

where the $S$ values have been corrected with regard to the initial signal, and $D = \Psi_{1A}\Psi_{2B} - \Psi_{2A}\Psi_{1B}$ is the determinant of the $\Psi$ matrix.

The study of the effect of experimental errors on the evaluated concentrations will be based on the hypothesis that errors affect the measured signals due to the uncertainties in time, signal measurement, experimental conditions, and so on. The error in calibration will affect the proportionality constants; for instance, the error in $\Psi_{1A}$ is given by Equation (127):

$$\Psi_{1A} = \frac{S_{1A}'}{[A]_{cl}} + \varepsilon_{1A} = \Psi_{1A} + \varepsilon_{1A}$$  \hspace{1cm} (127)$$

where $[A]_{cl}$ is the concentration of A species in the calibration. By introducing all the measurement errors in Equation (126), expressions for the error concentrations are given by Equations (128) and (129):

$$\varepsilon_{1A} \equiv \frac{\Psi_{1B}}{\Psi_{1B}} \left[\frac{[B]_{im}}{[B]_{cl}}\right]^{\varepsilon_{2B}} + \frac{[A]_{im}}{[A]_{cl}}^{\varepsilon_{2A}} - \varepsilon_2$$

$$\varepsilon_{2B} \equiv -\frac{\Psi_{2B}}{\Psi_{2B}} \left[\frac{[B]_{im}}{[B]_{cl}}\right]^{\varepsilon_{1B}} + \frac{[A]_{im}}{[A]_{cl}}^{\varepsilon_{1A}} - \varepsilon_1$$  \hspace{1cm} (128)$$
These equations indicate that the concentration errors depend on: the value of the uncertainty in the measurements; the value of the proportionality constants, and thus on the experimental design; and the relationship between the concentrations in the calibration and the sample. Besides, the systematic errors can be partially compensated when they are in the same kinetic curve or reinforced when they are at the same time in the calibration curves. On the other hand, the systematic errors affect each substance in an opposite way, that is, when the error of A is positive the error of B will be negative and vice versa. Finally, errors in the first experimental point will have a larger effect because the proportionality constants of the second calibration time, $\Psi_{2A}$ and $\Psi_{2B}$, are higher than those of the first calibration time, $\Psi_{1A}$ and $\Psi_{1B}$.

The optimal experimental design will be the one that makes the determinant $D$ the maximum. Equation (130) gives:

$$D = s_{AB} \left( (1 - e^{-k_A t_1}) (1 - e^{-k_B t_1}) - (1 - e^{-k_B t_1}) (1 - e^{-k_A t_1}) \right)$$

This determinant is maximum when $t_1$ is the highest possible, and $t_1$ is given by Equation (131):

$$t_1 = \frac{\ln(k_B/k_A) + \ln(1 - e^{-k_A t_1})/\ln(1 - e^{-k_B t_1})}{k_B - k_A}$$

A drawback of proportional equations is that although a fairly large number of data points is obtained, only a small fraction, two in a binary mixture, are used in the computation, thereby limiting precision. On the other hand, although theoretically there is no limitation on the number of components that could be determined, a practical limit only allows the resolution of mixtures of up to four components with acceptable errors, as long as their rate constants are sufficiently different. The high propagation of experimental errors, as shown in Equations (128) and (129), imposes the restriction. However, this method provides better precision and accuracy than other differential methods.\(^{(25)}\)

### 3.3.2 Regression Methods

Experimental data can be condensed by fitting them to a model that depends on adjustable parameters. Generally, these parameters are the rate constants in the calibration step and the analyte concentrations during the determination procedure. An objective function must be chosen to measure the agreement between data and model response with regard to a particular set of parameter values. The fitting problem reduces to a minimization process that searches the set of parameter values that minimize the objective function. Finally, statistical tools are needed to measure the uncertainty of the determined parameters.

#### 3.3.2.1 Least-squares Regression

The least-squares fitting is a maximum likelihood estimation of the parameters, provided that the measurement errors are independent and normally distributed.\(^{(4)}\) For a single response, the least-squares can be written as in Equation (132):

$$x = \sum_{i=1}^{N} w_i (Y_i - S_i)^2 = \sum_{i=1}^{N} w_i r_i^2$$

where $w_i$ is the weight assigned to the $i$th point, $Y_i$ the experimental signal, $S_i$ the signal value predicted by the model, and $r_i$ the residual or difference between the experimental and predicted values.

Conventionally, the weight of an experimental point, $w_i$, has been taken as inversely proportional to its variance, $\sigma_i$, for uncorrelated measurements, as given by Equation (133):

$$w_i = \frac{1}{\sigma_i^2}$$

In this way, the more uncertain experimental data are considered less. Another kind of weight arises from the use of a transformed variable,\(^{(2)}\) $Z$, from the raw experimental variable, $Y$. Equation (134) gives:

$$w_i = \frac{(1/\sigma_i^2)}{(dZ/dY)^2}$$

For instance, when a logarithmic transformation is performed the weights must be $w_i = (S_i/\sigma_i)^2$. It can be shown that the transformation causes a distortion in the informative structure of the data\(^{(26)}\) and that weights given in Equation (134) restore the original structure.

The minimization of the least-squares function can be done using several methods.\(^{(27)}\) The Newton–Raphson method is based on the Taylor’s series expansion of the gradient, $G$, as shown by Equation (135):

$$G(P + \Delta P) = G(P) + H(P)\Delta P + \ldots$$

where $P$ and $\Delta P$ are the parameter and the parameter increment vectors, and $H$ the Hessian matrix. By neglecting the higher-order terms and setting the gradient equal to zero, Equation (135) can be easily solved for the value of $\Delta P$ that leads to the desired minimum as shown in Equation (136):

$$\Delta P = -H(P)^{-1}G(P)$$
In general, the higher-order terms in Equation (135) are not negligible, and hence an iterative procedure has to be used. In least-squares regression problems, the elements of gradient and Hessian are given by Equations (137) and (138):

\[
g_i = \frac{\partial \chi}{\partial P_i} = -2 \sum_{k=1}^{N} w_k \frac{\partial S_k}{\partial P_i} r_k \tag{137}
\]

\[
h_{ij} = \frac{\partial^2 \chi}{\partial P_i \partial P_j} = 2 \sum_{k=1}^{N} w_k \frac{\partial S_k}{\partial P_i} \frac{\partial S_k}{\partial P_j} \tag{138}
\]

where the second-order derivative terms, in the Hessian element, have been dismissed. Using this approximation in Equation (136) leads to the iterative expression shown in Equation (139):

\[
P_{n+1} = P_n + (X^TWX)^{-1}X^TWr \tag{139}
\]

where \( W \) is the diagonal matrix of weights, \( r \) the residuals vector, \( X \) the Jacobian matrix \((x_{ij} = \partial S_i / \partial P_j)\), and \( X^T \) denotes the transpose of the matrix \( X \). This procedure is often called the Gauss–Newton method.

The least-squares function of a linear model is quadratic and the minimum is reached in a single step. Then, taking the origin as the initial parameters vector, Equation (139) leads to Equation (140):

\[
P^* = (X^TWX)^{-1}X^TWY \tag{140}
\]

where \( P^* \) is the optimum parameter vector.

An important part of the optimization process is to determine the uncertainty of the estimated parameters.\(^{(26)}\) From the linearized model shown in Equation (136), the variance–covariance matrix, \( C \), that contains estimates of the errors in the parameters, is given by Equation (141):

\[
C = \frac{\chi^*}{N - n} H^{-1} \tag{141}
\]

where \( \chi^* \) is the value of the least-squares objective function at the minimum, \( N \) the number of experimental points and \( n \) the number of fitted parameters. Thus, the estimated standard deviation in the \( i \)th parameter is given by Equation (142):

\[
\sigma_{P_i} = \sqrt{C_{ii}} \tag{142}
\]

It is important to realize that the Hessian matrix \( H \) is a curvature matrix of the least-squares objective function, and low curvatures around the optimum result in high uncertainties in the estimated parameters. The curvature decreases when the correlation of predictor variables (the columns of the \( X \) matrix) increases. In multicomponent analysis using kinetic data, the correlation could be high because the kinetic signals usually have similar profiles, leading to low curvatures and large uncertainties.

Obviously, the problem increases when the rate constants become more similar.

3.3.2.2 Error Sensitivity Analysis in Least-squares Regression

It is well known that the accuracy of a determination can be ruined by small systematic errors in the experimental conditions such as reagent concentration, time, temperature, or calibration parameters. To evaluate the influence of uncertainties in experimental variables, an error sensitivity analysis must be performed. The error sensitivity of the parameter \( P \) with respect to an error in the variable \( X \) can be obtained using Equation (143):\(^{(29)}\)

\[
\delta P_X = \frac{dP^*}{dX} = \frac{h_{PX}}{h_{PP}} \tag{143}
\]

where \( P^* \) is the optimized parameter, and \( h_{PX} \) and \( h_{PP} \) are the corresponding elements of the Hessian matrix. This equation gives the estimated error in the determination of \( P \) by least-squares regression, when the systematic error in the variable \( X \) equals unity. It must be noted that \( X \) can be any variable having an influence on the value of the experimental points, and an explicit relationship between \( X \) and \( P \) is not required. In this way, the relative systematic error in \( P \) owing to a relative error in \( X \) will be given by Equation (144):

\[
\varepsilon_{rP} = \frac{h_{PX} X}{h_{PP} \overline{P} \varepsilon_{rX}} \tag{144}
\]

When several experimental variables are affected by errors, the propagation of systematic errors must be applied as in Equation (145):

\[
\varepsilon_P = \delta P_X \varepsilon_{X_1} + \delta P_X \varepsilon_{X_2} \tag{145}
\]

Finally, when several parameters are simultaneously fitted, the propagation of errors rule leads to a system of linear equations. Equations (146) and (147) show that for two parameters and one variable we have:

\[
\varepsilon_{P_1} = \delta P_1 \varepsilon_{X} + \delta P_1 \varepsilon_{P_1} \tag{146}
\]

\[
\varepsilon_{P_1} = \delta P_1 \varepsilon_{X} + \delta P_1 \varepsilon_{P_1} \tag{147}
\]

The resolution of this system will yield the propagated errors in the parameters.

Table 5 shows the relative error sensitivities for the determination of the initial concentration and rate constant for a second-order reaction at several reagent concentrations. The rate constant, \( k \), is more affected by systematic errors than the initial concentration. On the other hand, error propagation is, in general, lower when pseudo-first-order experimental conditions are used.

3.3.2.3 Principal Component Regression

Least-squares regression techniques can be misused if care is not
Eigenvector decomposition can be performed using several algorithms. The nonlinear iterative partial least-squares (NIPALS) method is a simple algorithm that extracts one factor at a time, employing an iterative procedure to obtain the loading and score vectors from the residual matrix, obtained after estimation of the previous factors. In a second step, the Y-variables are regressed on T. Since the principal components are uncorrelated, the regression can proceed factor by factor, choosing only the factors that involve real variability of the X matrix and rejecting those that only account for noise. The PCR estimate of the parameters, using the most relevant factors, can be written as Equation (149):

$$ P_{PCR} = V(T^T T)^{-1} T^T Y $$

(149)

Since the scores in T are uncorrelated, Equation (150) gives:

$$ T^T T = \text{diag} \left( \frac{1}{v_m} \right) $$

(150)

where $v_m$ is the eigenvalue of the $m$th factor. The eigenvalues show how much variability each factor removes from X.

The main advantage of PCR is that it allows redundant factors and noise variability to be removed by performing a dimension reduction. However, an important problem is how to define the number of relevant factors. A good calibration practice is to extract more factors than are expected to be needed, and afterwards eliminate those that appear to be irrelevant or unreliable. Finally, it is important to realize that PCR coincides with multivariate least-squares regression when all factors are used.

3.3.2.4 Partial Least-squares Regression This method differs from PCR by including the dependent variable in the data compression and decomposition operations; this makes the method more complex as two loading vectors are required to provide orthogonality of the factors. The factors, called latent variables, are chosen in order to use X and Y efficiently, and provide a strong fit between them. In this way, the PLS factors can be seen as modified principal components improving the correlation. In the PLS algorithm, two principal component analyses are carried out, one for X and another for Y, by applying NIPALS to the column-centered matrices X and Y as shown in Equations (151) and (152):

$$ X = TV^T + E $$

(151)

$$ Y = UB^T + F $$

(152)

where V and B are the loading matrices and T and U the score matrices for X and Y, respectively. A linear

Experimental conditions were: $[A]_0 = 0.01, s = 100, k = 1$ and 120 experimental points were used taking 95% extent of reaction. Relative error in blank signal, $S_b$, was referred to $S_{an}/2$. Applied in ascertaining the suitability of the model for describing the data. On the other hand, the correlation between the kinetic behavior of the different substances limits the number of species that can be simultaneously determined. Principal component regression (PCR), partial least-squares (PLS) regression and KF regression are procedures that have been applied to obtain kinetic parameters from noisy data, with models that are not well fixed, and to reduce the effects of correlation.

A major drawback of multiple least-squares is derived from the increase of collinearity among the predictor variables (the columns of the $X$ matrix). Collinearity arises from similar signal responses for some analytes, from badly conditioned experimental designs, or from an overdimensioned number of predictor variables. All these problems increase when a large number of independent variables is involved. In this case, the Hessian becomes nearly singular and the inversion leads to a large variance in the parameters, as shown in Equation (141). This is a common situation when applying kinetic methods, due to the similar behavior of time-dependent signals in multicomponent analysis. PCR copes with this problem by performing a dimensional reduction by a principal component analysis of $X$.

The principal component analysis involves the rotation of coordinate axes to orientate them in the direction that maximizes the empirical variance of the predictor variables. The new axes are called eigenvectors or loadings, $V$, and the new predictor variables, principal components, scores, or factors $T$. These scores are not correlated and, thus, principal component analysis compresses $X$ to its most relevant factors $T$. The matrix $X$ must be mean column-centered, previously. The transformation is given by Equation (148):

$$ X = TV^T + E $$

(148)

where $E$ is the matrix of residuals of $X$ generated when the number of factors that account for the variability in $X$ is less than the number of original predictor variables. Thereby, the common structures in $X$ are compressed into a stabilized, more easily interpretable model, leaving out much of the noise as residuals.
relationship as shown in Equation (153) between latent variables is set to enhance the correlation between the predictors and the response:

\[ U = TQ + D \]  

(153)

where \( Q \) is a diagonal matrix that accounts for the correlation between latent variables, and \( D \) is the residuals matrix. Equation (154) relates \( T \) to \( Y \):

\[ Y = TC^T + F \]  

(154)

Finally, the estimated parameters can be obtained by using the expression in Equation (155):

\[ P = W(V^TW)^{-1}C^T \]  

(155)

where \( W \) is the matrix of \( X \)-factor weights that correlate each \( u \) vector with \( X \) residuals. Equation (156) gives:

\[ w_j = cE_j^Tu_j \]  

(156)

where \( c \) is the scaling constant that makes the length of the final \( w_j \) vector equal to 1, and \( E_j \) is obtained from Equation (157):

\[ E_j = X - \sum_{i=1}^{j-1} t_ip_i^T \]  

(157)

and at the beginning \( E_1 = X \).

When all factors are used, the PLS predictor is equal to the least-squares predictor. PLS and PCA are the so-called soft-modeling methods in which an empirical model is derived from the data. The model is built up from a number of calibration samples. The use of these methods in kinetic problems is growing due to their efficiency in dealing with problems from incomplete models, imprecise data sets, and interactions among the components.

3.3.2.5 Kalman Filter  The KF is a recursive algorithm that introduces a new experimental point at each calculation step, and optimizes the point residual and the mean error of the estimates of the parameters (state variables). The linear KF requires the model to be linear with respect to the state variables, and has been used for pseudo-first-order kinetic determinations.

In this algorithm, as in linear least-squares, the rate constants must be well-known and are supposed to be invariant from run to run. This assumption is a serious drawback that affects the results, since the pseudo-first-order rate constants are functions of many experimental factors (temperature, pH, ionic strength, and so on).

The extended KF must be used with nonlinear models. This algorithm is based on a linear term truncated Taylor's series expansion about the current estimate of the parameters. The extended KF is a statistically nonoptimal procedure, and more prone to the influence of the initial guesses of the parameters than the linear form, due to the inherent error caused by truncation of higher-order terms. Rate constants can be included among the parameters to be estimated and adjusted in the process of the filter, as in the NLS method. Both the least-squares and the KF algorithms are model-based, or hard-modeling methods, in which accurate model information is indispensable to obtain good results.

The extended Kalman algorithm for time-invariant parameters can be set out in the following steps:

1. Initialize \( P(0) \) and \( x(0) \), \( P \) being the error covariance matrix, related to the inverse of the Hessian in least-squares, and \( x \) the vector of the parameters to be estimated. It is recommended to choose for \( P(0) \) a diagonal matrix with very large diagonal elements, expressing the large uncertainty in the chosen starting values of \( x(0) \).

2. Compute the linearized measurement function vector, \( h(j) \), that coincides with the \( j \)th row of the Jacobian matrix as shown in Equation (158):

\[ h(j)_k = \frac{\partial S[x(j - 1)]}{\partial x_k} \]  

(158)

where \( S \) is the model estimated signal.

3. Update the Kalman gain vector, \( k(j) \), and the error covariance matrix using Equations (159) and (160):

\[ k(j) = \frac{P(j - 1)h(j)}{h(j)^T[P(j - 1)h(j) + V(j)]} \]  

(159)

\[ P(j) = P(j - 1) - k(j)[h(j)^TP(j - 1)] \]  

(160)

where \( V(j) \) is the variance of the \( j \)th experimental point. The Kalman gain vector is chosen to be the gain or blending factor that minimizes the a posteriori error covariance matrix \( P(j) \).

4. Predict the value of the signal at point \( j, S(j) \), with the parameters obtained in the \( j - 1 \) cycle, and evaluate the residual or innovation, \( I(j) \), using Equation (161):

\[ I(j) = Y(j) - S[x(j - 1)]_j \]  

(161)

5. Update the predicted parameters using Equation (162):

\[ x(j) = x(j - 1) + k(j)I(j) \]  

(162)

6. Return to step 2, until all experimental points have been included.

When the parameters to be estimated are not constant but vary with time, a dynamic KF can be used in which a new step must be included between steps 5 and 6.

\(^b\) ABA, aminobenzoic acid. Coupling reaction of diazotized sulfanilamide with the \(o\)-, \(m\)- and \(p\)-ABAs.

The pseudo-first-order rate constants for the reactions performed at pH = 3.9 were \(k_o = 4.67, k_m = 9.24,\) and \(k_p = 1.45;\) these values are highly affected by pH variations.

\(^c\) NLS regression using the Powell algorithm.\(^{27}\)

\(^d\) Extremely large absurd values.

5’. Extrapolate the parameters vector and the error covariance matrix using Equations (163) and (164):

\[
x(j + 1|j) = F(j + 1, j)x(j|j) + w(j)
\]

\[
P(j + 1|j) = F(j + 1, j)P(j|j)F^T(j + 1, j) + Q(j)
\]

where the matrix \(F(j + 1, j)\) is the system transition matrix, which describes how the system state changes from time \(t_j\) to \(t_{j+1}\). The vector \(w(j)\) consists of the noise contribution to each of the parameters, and \(Q(j)\) is the variance–covariance matrix of the system noise which contains the variance of \(w\).

In line with KF literature, in the above description the common notation has been used in spite of the difference with the notation in other multivariate methods. The results of the KF depend on the initial estimates of the parameters. On the other hand, they rely on the initial guesses for the variance of the corresponding estimated values, and on the variance of the measurement noise.

Table 6 shows the average absolute relative error produced in the simultaneous determination of two substances using spectral-kinetic data, and different regression methods with three different numbers of wavelengths.\(^{35}\) For the NLS the estimated error was extremely large for some of the mixtures. On the other hand, PLS and extended KF gave satisfactory results if the difference of the rate constants was large enough \((m\text{-ABA}/p\text{-ABA mixture}).\) However, for closer rate constants \((o\text{-ABA}/m\text{-ABA mixture}),\) a larger number of wavelengths must be used to improve the results. It can be deduced that PLS gave better results than the KFs, and that the extended KF performed better than the linear one for these experimental data. Besides, the more wavelengths used, the less the influence of the errors on the rate constants. Moreover, the influence of the number of wavelengths on the extended KF was not so significant as in the linear KF, which was attributed to the correction of the rate constants.

Differential Rate Determinations

M. Dolores Pérez-Bendito
University of Córdoba, Spain

1 INTRODUCTION

Multicomponent analysis is one of the main goals of the modern analytical chemistry. The simultaneous or sequential determination of several analytes in the same sample can be accomplished without or with physical separation in space (e.g. in chromatographic techniques). Multicomponent kinetic determinations, traditionally called “differential reaction rate methods”, are based on the different rate at which two or more species in solution react with a common reagent. They allow the variation of the analytical signal yielded by each species to be “separated” on a different timescale, thereby avoiding the need to separate the components physically. Separation techniques are usually time-consuming and may result in sample loss and contamination. Hence differential rate methods are of great interest in the context of kinetic methods of analysis as they are effective alternatives to multicomponent analysis, especially when only a few components in a mixture are to be determined. The principles and features of differential rate methods have been compiled in two books on kinetic methods and also in several reviews on the topic.

Classical differential rate methods, developed in the 1960s–1970s, were based on simple mathematical equations and required only a few kinetic data for application. They were only applied to first- or pseudo-first-order reactions in order to resolve binary mixtures with a rate constant ratio above about three. Modern differential rate methods combine rate discrimination with mathematical and/or spectral/instrumental discrimination to provide much better performance and a wider scope of application by virtue of their using much greater amounts of information. The development of new computerized data processing methods has been the key to both the implementation of variably complex mathematical algorithms (kinetometric approaches) and the handling of multidimensional data such as the multiwavelength readings provided by diode array spectrophotometers. These methods have expanded the scope of conventional reaction rate methods to reaction orders higher than first- or pseudo-first order, rate constant ratios near unity and even mixtures exhibiting mutual kinetic effects (synergism). As the efficiency of mathematical discrimination and/or spectral discrimination increases, the need for kinetic discrimination (based on the difference between
reaction rates) is reduced, so much so that a system with completely overlapped kinetics can be effectively resolved provided that some spectral difference exists at the wavelength considered. These methods thus afford the kinetic resolution of mixtures of analytes on the basis of spectral differences rather than kinetic differences; as a result, the designation “multicomponent kinetic methods” is more appropriate than differential reaction rate methods. Finally, rate discrimination can also be combined with the physicochemical discrimination provided by micellar systems.

The potential of these modern methods can only be fully exploited for analytical purposes by using automated methods, which provide results of increment quality and enable multicomponent determinations in routine analyses. Various automated approaches (continuous and stopped-flow (SF) included) according to the way sample and reactants are mixed are possible. Their performance in terms of mixing expeditiousness and homogeneity depends on the rates of the reactions involved, especially with fast reactions (viz. with lifetimes of a few milliseconds or shorter).

This article describes currently available methods for kinetic multicomponents analysis that provide high-quality results and encompass a wide range of analytes in mixtures and analyte concentration ratios when used in combination with an automated method suitable for routine analyses.

2 THEORETICAL AND METHODOLOGICAL BACKGROUND

2.1 General Considerations

Differential kinetic methods have traditionally focussed on mixtures of components reacting at slightly or strongly different rates; however, methods for mixtures exhibiting small rate differences account for the majority of the work in this field. The analytical applicability of these methods is dependent on the relative values of the rate constants and on the ratio between the concentrations of the mixture components.

Let A and B be two substances in a mixture that react with a reagent R to yield two products (P and P’) which, though different in nature, are essentially similar with regard to the analytical property to be measured, according to the reactions shown here (Equations 1 and 2):

\[ A + R \rightarrow P \]  \hspace{1cm}  (1)

\[ B + R \rightarrow P' \]  \hspace{1cm}  (2)

where \( k_A \) and \( k_B \) are the rate constants for reaction of A and B, respectively, which are first-order with respect to each mixture components (i.e. \([R]_0 \gg [A]_0 \) and \([R]_0 \gg [B]_0 \)).

If the mixture to be resolved exhibits a large difference between the reaction rates (i.e. \( k_A/k_B \) is sufficiently different from unity), then the analysis is quite simple because each species can be treated separately. In this case, one can assume that, over any time interval, only one species will react since the other either will have already reacted completely or be reacting so slowly that it could hardly interfere with the reaction of interest.

If \( k_A > k_B \) but B reacts to an appreciable extent over a given time interval, then the ratio of their rate constants, \( k_A/k_B \), needed to obtain a given error in the concentration of A can be determined from the ratio of the respective first-order rate integrated equations for both components (Equations 3 and 4):

\[ \ln \left( \frac{[A]_0}{[A]_T} \right) = k_A t; \hspace{0.5cm} \ln \left( \frac{[B]_0}{[B]_T} \right) = k_B t \]  \hspace{1cm}  (3)

i.e.

\[ \frac{\ln([A]_0/[A]_T)}{\ln([B]_0/[B]_T)} = \frac{k_A}{k_B} \]  \hspace{1cm}  (4)

This equation is time-dependent and relates the extent of both reactions to their rate constants. If a maximum error of 1% is considered to be acceptable (i.e. if there is still 1% of A present when less than 1% of B has reacted) then the \( k_A/k_B \) ratio in Equation (4) should be at least 463. In practice, a minimum ratio of 500 is commonly adopted.

As the ratio of the two rate constants, \( k_A/k_B \), approaches unity, the errors in the estimated concentrations of the components in the mixture become larger. Hence, traditional methods for small rate differences involve the selective determination of the more rapidly reacting species, either by altering the kinetics of a system via appropriate changes in the reaction conditions (e.g. temperature, solvent, reactant concentrations) or by masking the species with a suitable inhibitor. The concentration of the second species can be obtained by a similar approach or by the difference from a determination of the sum of the two concentrations. However, the most frequently used methods for the simultaneous determination of species with small differences in their rate constants are based on mathematical approaches for systems having unalterable rate constants (such constants often can not be separated to a sufficient degree by either of the above-described types of method). The most popular approaches to differential rate determinations
historically have been logarithmic extrapolation methods and the method of proportional equations (classical methods). \(^{(2)}\)

These methods are available for various reaction orders \(^{(2)}\) of which the pseudo-first is the most widely considered. They assume the simultaneous contribution of the two-reaction component to the analytical signal according to Equations (1) and (2). If the pseudo-first order reaction rates of two substances are different and independent of each other (i.e. if no mutual kinetic effects are present), then the sum of the contribution of A and B at time \(t\), \(C_t\), is given by Equation (5)

\[
C_t = [A]_t + [B]_t = [P]_\infty - [P]_t = [A]_0 \exp(-k_A t) + [B]_0 \exp(-k_B t)
\]

where \([A]_t\) and \([B]_t\) are obtained, respectively, from the exponential forms of the integrated rate equations (Equation 3). \([P]_\infty\) is the maximum total product concentration, which is usually measured after allowing the reaction to proceed for a sufficiently long time and in itself a measure of the total initial concentration of reactants, \([A]_0 + [B]_0\). \([P]\) can be replaced with a measurable property proportion total to the product concentration such as the absorbance, fluorescence or chemiluminescence intensity, or potential. Equation (5) is the basis for application of classical and some kinetometric methods.

3 KINETIC DISCRIMINATION: CLASSICAL METHODS

3.1 Logarithmic Extrapolation and Proportional Equations

The logarithmic extrapolation method is the most commonly used graphical linear method for the simultaneous kinetic determination of species. The method is based on Equation (5) and uses plots of log \(C_t\) or log([P] \(\infty\) - \([P]_t\)) as a function of time (Figure 1). The result is a curve unless \(k_A = k_B\), in which case a straight line is obtained. If species A disappears at a higher rate than B (i.e. if \(k_A > k_B\)), then \([A]_t \to 0\) and the curve eventually becomes a line (Figure 1), Equation (6)

\[
\log C_t = \log([P]_\infty - [P]_t) = \log [B]_0 - \frac{k_B t}{2.303}
\]

The intercept of the curve provides the initial concentration of B, \([B]_0\), that of the other component, \([A]_0\), being obtained by difference once \([A]_0 + [B]_0\) has been determined from \([P]_\infty\). If a photometric detection technique is applied, then Equation (6) can be written as Equation (7):

\[
\log(D_\infty - D_t) = \log \varepsilon_\infty [B]_0 - \frac{k_B t}{2.303}
\]

where \(D_\infty\) and \(D_t\) are the absorbances measured after the reaction has developed to completion and after a time \(t\) near the start of the linear region, and \(\varepsilon_\infty\) is the molar absorptivity of B (known beforehand).

This method features several advantages, namely: (1) no prior knowledge of the rate constant of A or B is necessary; (2) it is less prone to error as the linear plot is constructed from several points; (3) it can be applied to ternary mixtures provided the rate constants of the three components are sufficiently different (even in the presence of synergistic effects) as it is not limited to pseudo-first-order reactions; (4) rate constant ratios as low as five are acceptable under certain conditions (e.g. with favorable concentration ratios and if somewhat large errors are acceptable). However, at least 99% of the more reactive species should be consumed in the process if valid data are to be obtained and the total initial concentration of all the species involved should be known for the method to be applicable. In addition, the method is somewhat laborious as it entails the continuous recording of the measured property and obtaining the required \([P]_\infty - [P]_t\) values from the resulting curve. For two reactions following second-order kinetics in which \([R]_0 \approx [A]_0 + [B]_0\), the reaction rate can be expressed by Equation (8)

\[
-\frac{d[R]}{dt} = \frac{dx}{dt} = k_A[R][A]_0 + k_B[R][B]_0
\]

where \(x\) is the amount of R consumed at any time \(t\). If A reacts faster than B, then, when \([A]\) has reacted essentially to completion, Equation (8), after integration, gives Equation (9)

\[
x = k_A[B]_0[(R)_0 - x]t + [A]_0
\]

\([A]_0\) is then determined from the extrapolated intercept at \(t = 0\) of a plot of \(x\) versus \([(R)_0 - x]t\).

The proportional equation method is a mathematical approach of wide use for the resolution of mixtures of closely related species; it is usually less time-consuming.
than the previous method (especially if a microcomputer is used) and in the most cases requires no prior knowledge of the total concentrations of the mixture component. A rate constant ratio of four is usually acceptable and the ease with which the method can be automated make it suitable for fast reactions. However, it cannot be applied to processes subject to synergistic effects because the measured property must be additive in nature. On the other hand, the rate constants must be carefully calculated; if the reaction involves complex kinetics, then the applicability of the method relies on the accurate calculation of the different proportionality constants.

The practical procedure for pseudo-first rate reactions entails measuring $C_i$ at two or more reaction times and formulating two Equations (10) and (11) similar to Equation (5):

$$[P]_i - [P]_0 = [A]_0 \exp(-kA_1 t) + [B]_0 \exp(-kB_1 t) \quad (10)$$
$$[P]_\infty - [P]_0 = [A]_0 \exp(-kA_2 t) + [B]_0 \exp(-kB_2 t) \quad (11)$$

the resolution of which provides the initial concentrations of the different components as functions of their respective rate constants (known beforehand).

Not only time, but any other experimental variable such as temperature or one related to the solvent or the physicochemical characteristics of the reactants can be used to formulate the simultaneous equations from which the required concentrations are to be calculated. Thus, the general equations for a binary mixture will be of the form (Equations 12 and 13)

$$f_1 = k_{A_1}[A]_0 + k_{B_1}[B]_0 \quad (12)$$
$$f_2 = k_{A_2}[A]_0 + k_{B_2}[B]_0 \quad (13)$$

where $f$ is any measurable parameter determined under two different sets of conditions, and $k_{A_1}$ and $k_{A_2}$ are empirical or proportionality constants obtained separately for component A under different conditions in the same way as $k_{B_1}$ and $k_{B_2}$ are obtained for component B. Although any experimental variable is usable provided $k_{A_1}k_{B_2} \neq k_{A_2}k_{B_1}$, the optimum results are obtained with $k_{A_1}/k_{B_1} > 1$ for one set of conditions and $k_{A_2}/k_{B_2} < 1$ for the other.

Applications of these classical methods, most of which involve the resolution of binary mixtures of metal ions, have been compiled.\(^5\)

### 3.2 Synergism

Both classical differential reaction-rate methods and new approaches rely on the assumption that the reaction rates of the species in the mixture are independent of each other. When this is not so, the mixture is said to be subject to a mutual kinetic or synergistic effect. Although synergism is not a frequent phenomenon, it is the chief source of error in differential kinetic analysis and should therefore be duly studied and controlled to ensure the accurate resolution of mixtures. Only the second-order logarithmic extrapolation and the Connors graphical extrapolation methods\(^5\) are applicable in this event; in fact, if the cause of synergism is known, the reaction conditions are usually modified to avoid it.

Several approaches to the simultaneous resolution of mixtures subject to synergism have been reported. One is based on the Connors graphical interpolation method and involves using equations that can be formulated on the basis of any experimental parameter provided it is proportional to the concentration of the species concerned.\(^6\) The method involves matching the concentration–time profile of a simple mixture to that of a reference mixture so that the initial concentrations of sample and reference are identical. Consider a mixture of two components, A and B, which react under pseudo-first order conditions with a reagent R to yield the same product, P. First, the concentration of P is measured as a function of time ($[P]_0$). Next, reference mixtures are reacted under the same conditions and $[P]_r$ is measured as a function of time. Once the concentration–time profiles for the sample and reference have been fully matched throughout the time range, $[P]_s = [P]_r$ and hence $[A]_s = [A]_r^0$ and $[B]_s = [B]_r^0$.

In practice, the calculation of $[A]_r^0$ involves the construction of several calibration graphs from plots of the final absorbance of component B in the presence of different known amounts of A. The intercepts of these plots are dependent on the concentration of component A. The concentration of B is calculated from the plots of the difference in the initial rates (IR) of the concentration–time curves for the sample and several reference solutions, viz. $\mu IR - \mu IR$ versus B. The method is also useful at low rate-constant ratios, which often pose problems in differential rate analyses. Its performance was evaluated with fast direct complexation reactions between cobalt and nickel and pyridoxal thiosemicarbazone (PTSC), which were subject to a synergistic effect, using a customized SF mixing module. The rate constant ratio was $k_{Ni}/k_{Co} = 2.63$. The determination of nickel in real samples entailed the prior determination of their cobalt content by applying the above-described procedure for calculation of $[A]_s^0$. Once this concentration had been evaluated, different known amounts of nickel in the range 1.0–5.0 µg mL\(^{-1}\) were added to a sample aliquot containing a known cobalt concentration between 1.0–2.5 µg mL\(^{-1}\), and reacted with PTSC.
4 MATHEMATICAL DISCRIMINATION: KINETOMETRIC METHODS

As noted in section 3, classical differential kinetic methods are based on simple mathematical equations and require only a few data points and rate constant ratios higher than about four for binary mixtures. The inception of digital computers has facilitated the use of multipoint methods that provide more information by exploiting the whole kinetic curve. This trend has materialized in the application of mathematical algorithms based on specific kinetic models which allow the concentrations of two or more analytes in mixtures to be determined, whether or not the rate constants and reactions order involved are known beforehand, and for $k_A/k_B$ ratios closer to unity.

Kinemetrical methods are a concept of increasing interest as a result of dynamic systems frequently exhibiting a nonlinear relationship that can readily be modeled with computational aids. Curve fitting and related algorithms have proved useful in simultaneous kinetic determinations. In this section, the usefulness of recent kinemetrical approaches such as Kalman filtering and artificial neural networks (ANN) is also discussed.

4.1 Multipoint Curve-fitting Methods

Curve-fitting methods compute values of parameters that represent the best fit of some mathematical model to signal–time data. Although curve fitting methods excel over direct computation methods (classical methods) for processing linear responses (pseudo-zero-order processes), they are also especially suitable for nonlinear responses. Fits to nonlinear responses can be used to predict or extrapolate data obtained in another time region of the process.

In multipoint curve-fitting methods for kinetic analysis of mixtures signal–time data pairs collected over a fixed period (7–8 half-lives of the slowest reacting component) are fitted to a mathematical model descriptive of the kinetic behavior of the mixture. The model frequently involves monitoring two or three pseudo-first-order reactions simultaneously through absorbance changes. The absorbance estimates as $D_{\infty} - D_0$ ($D_{\infty}$ and $D_0$ being the absorbances at infinite and zero time, respectively) for each component, which result in the best least-squares fit to the experimental model, are used to compute the concentration of each component. This requires a prior knowledge of the pseudo-first-order rate constant of each component and the absorptivity of its product; also, no mutual kinetic effect should be present. This approach also affords satisfactory results from data processed over two half-lives of the slower reacting component by using nonlinear and multiple linear curve-fitting methods that yield virtually identical results.

Other reported methodologies for the resolution of mixtures of species include a new algorithm developed by Schechter to resolve binary mixtures which requires no prior knowledge of the reaction orders or rate constants of the species involved and was tested on simulated data only. In addition, it allows the concentrations of the mixture components to be determined over broad ranges and the corresponding rate constants and reaction orders to be calculated. The algorithm, however, is somewhat less precise with reaction orders of exactly unity.

4.2 Kalman Filtering

Kalman filtering is an alternative curve-fitting approach that is gaining increasing interest in various fields of analytical chemistry and can be used to compute analyte concentrations or activities in enzymatic reactions. It is one of the most powerful algorithms available today for the simultaneous kinetic determination of species in mixtures (it is only surpassed by the neural network approach). Although it can be applied to single-component systems in order to calculate the initial concentration of the analyte and its first-order rate constant, its main applications are the correction of errors associated with between-run variations and, especially, simultaneous kinetic determinations. Thanks to its recursive nature, determinations can be performed in real time (thereby expediting the process) provided half lives allow it. It has proved useful for fitting linear and nonlinear (extended Kalman filter) kinetic data, depending on whether or not the rate constants of the two reactions are known beforehand (although the results are better when they are).

When the algorithm is used in its nonlinear form, its performance relies heavily on the initial parameter chosen and the number of iterations performed. Figure 2 illustrates how the Kalman filter can be used in multicomponent kinetic analysis. It is based on the rate equation for a binary mixture (Equation 5), which, taking into account that $[P]_t = [A]_0 - [A] + [B]_0 - [B]$, and that $[P]$ is replaced with the total absorbance at time $t$, $D_t$, can be expressed by Equation 14

$$D_t = D_A[1 - \exp(-k_At)] + D_B[1 - \exp(k_Bt)] + C \quad (14)$$

where $D_A$ and $D_B$ and $k_A$ and $k_B$ are the net absorbance change and the pseudo-first-order rate constants for the two components, respectively, and $C$ is the contribution of the background absorbance.

Investigations have shown this algorithm to be superior to classical multicomponent kinetic methods such as those of logarithmic extrapolation, single point and proportional equations in many respects, especially with regard to the affordable rate constant ratios of reactions for a binary mixture, which can be closer to unity than in the above-mentioned classical methods. Such is the case with
the resolution of mixtures of cortisone and hydrocortisone by reaction with Tetrazolium Blue, the rate constant ratio of which is 1.8; the results compared favorably with those of classical methods\(^{12}\) (Table 1). Other mixtures of interest have also been satisfactorily resolved by the Kalman filtering.\(^{8}\) The use of this filter is not limited to pseudo first-order reactions; in fact, it also allows the resolution of mixtures of species following different kinetics (pseudo-first order and second order).\(^{13}\) The filter model used for this purpose was assessed both on simulated data and on the analysis of cysteine–ascorbic acid and glutathione–ascorbic acid mixtures, which were resolved with good accuracy over wide concentration ranges.

### 4.3 Artificial Neural Networks

ANN, also called computational neural networks (CNN), are increasingly used in analytical chemistry owing to
their ability to “learn” arbitrary nonlinear relationships between input and output spaces. An ANN can adapt itself autonomously to learn to recognize key features in a data set by repeatedly examining the same or similar data (the training set). ANNs can process information rapidly once the system is trained since the training process may require several hours of dedicated computer time depending on the particular training method. Several training methods have so far been used, the multilayer back-propagation method being the most widely employed so far.

The intrinsic features of ANNs afford the resolution of complex mixtures of species without the aid of spectral discrimination even if the systems involved have almost identical rate constants and exhibit synergism. By contrast, multivariate calibration methods (MCMs) such as nonlinear least-squares regression (NLR) and principal components regression (PCR) (and even the Kalman filter) are effective approaches to multicomponent kinetic determination when they combine kinetic and spectral discrimination (multiwavelength data) as shown in the next section.

The type and number of input data to be used in an ANN must be carefully chosen in order to ensure accurate results in the concentration of the mixture components, with minimal training costs. This has been accomplished by developing a straightforward methodology. For a binary mixture, Equation (14) can be fitted to Equations (15), the exponential function using NLR:

\[
\Delta D = \Delta D_I [1 - \exp(-\hat{k}t)] + C
\]

where \(\Delta D_I\) and \(\hat{k}\) are related to the true values of \(\Delta D_A\), \(\Delta D_B\), \(k_A\) and \(k_B\). \(\hat{k}\) can be considered the estimated rate constant for the mixture, which approaches \(k_A\) as the contribution of component A in the mixture increases and vice versa. \(\Delta D_T\) and \(\hat{k}\) values obtained from the kinetic curve for the mixture concerned were used as input to the ANN in order to obtain \(\Delta D_A\) and \(\Delta D_B\) or the mixture concentrations as output data by means of a very simple neural network architecture such as 2 : 4s : 2 l (which means 2 input data, 4 nodes in the hidden layer and 2 output data) with no prior knowledge of the respective rate constants. A scheme of the operating mode of an ANN corresponding to this architecture is shown in Figure 3.

This method was evaluated in the resolution of mixtures of 2-chlorophenol (2-ChPh) and 3-chlorophenol (3-ChPh) (rate constant ratio 1.4) with fairly good results: the values of the relative standard error of prediction (%SEP) were 4.23 and 6.20%, respectively, and the analyte concentration ratio range was 1 : 9–9 : 1. The performance of the method compared favorably with that of the Kalman filter (Table 2), which yielded relative errors near

to or about 10% in the resolution of 2-ChPh–3-ChPh mixtures in ratios from only 4:1 to 1:4.\textsuperscript{(14)} On the other hand, the proposed network architecture could be extrapolated to multicomponent analysis involving other kinetic situations such as species following different kinetics and the presence of synergistic effects. However, realizing the actual potential of ANNs in kinetic analysis requires further research.

5 SPECTRAL/INSTRUMENTAL DISCRIMINATION

The kinetic methods described in this section are also based on mathematical algorithms but rely heavily on the spectral discrimination afforded by multiwavelength data simultaneously provided by special optical spectroscopic devices (instrumental discrimination) such as diode array spectroscopy and the use of T-optic configurations. In general, kinetic discrimination is also present to a greater or lesser extent. However, the use of multiple wavelengths allows systems having rate constants too close for analysis by normal means to be successfully determined provided they exhibit any spectral differences. In some cases, instrumental discrimination enables the kinetic determination of mixture components irrespective of their kinetics provided sufficient spectral differences between them exist.

5.1 Multivariate Methods Using Multiwavelength Spectroscopy

The use of several wavelengths in kinetic experiments allows a greater variety of systems to be successfully analyzed. In fact, rapid-scanning spectrophotometers such as diode array models were the earliest instruments used to perform multiwavelength studies in multicomponent kinetic analysis.\textsuperscript{(5,10)} Full spectra can be recorded within a few seconds and simultaneous absorbance measurements made at several wavelengths instead of the absorbance–time data provided by conventional instrumentation are used as kinetic data. Thus, for a kinetic reaction involving a single component at an initial concentration \( C_0 \), absorbance changes with time can be expressed by Equation (16)

\[
A_{\lambda,t} = \varepsilon_\lambda C_0 [1 - \exp(-kt)] + B_{\lambda,C}
\]

For a mixture of two components 1 and 2 the absorbance is given by Equation (17)

\[
A_{\lambda,t} = \varepsilon_{\lambda,1} C_{0,1} [1 - \exp(-k_1 t)] \\
+ \varepsilon_{\lambda,2} C_{0,2} [1 - \exp(-k_2 t)] + B_{\lambda,C}
\]

Finally, for a mixture of \( n \) components, the simplified expression in Equation (18) holds:

\[
A_{\lambda,t} = \sum_{i=1}^{n} K_{(i,\lambda,t)} C_{0,i} + B_{\lambda,C}
\]

where \( A_{\lambda,t} \) is the absorbance measured at wavelength \( \lambda \) at time \( t \), \( \varepsilon_{i,\lambda} \) are the molar absorptivities of the components at the working wavelength, \( \ell \) is the pathlength, \( C_{0,1...n} \) are the initial concentration of each component, \( k_{1...n} \) are the respective rate constants, \( B_{\lambda,C} \) is the background absorbance at \( t = 0 \) and \( K_{(i,\lambda,t)} \) is a constant which depends on the particular component, its rate constant, wavelength and time.

Equation (18) is in itself a system of nonlinear equations that can be solved using various chemometric procedures such as the Newton–Gauss algorithm.\textsuperscript{(15)} Although the molar absorptivity, rate constant and concentration of each mixture component can be determined simultaneously, the most interesting application is the determination of rate constants and concentrations as a compromise between computational costs and the ability to introduce corrective actions for fluctuations in the rate constants arising from environmental factors (error-compensated method), taking into account that absorptivities can be calculated individually with greater accuracy from equilibrium data.

The resolution of cobalt and nickel in mixtures (including the estimation of the rate constant) using the ligand-exchange reaction with EGTA (ethylene glycol bis(2-aminoethyl ether \( N,N,N',N'\)-tetraacetic acid)) and PAR (4-(2-piridylazo)resorcinol) is one of the systems most widely used to validate this approach.\textsuperscript{(15)}

The application of the MCM to multicomponent kinetic analyses entails making several mixtures of known composition and recording their absorbances at different wavelengths and times. The wealth of information thus obtained must be reduced in order to abstract the analytically relevant information by using principal component analysis (PCA); also, calibration can be performed by using two similar MCMs such as PCR and partial least-squares regression (PLS). PLS breaks down both the measured data and the concentration calibration matrices into the product of two smaller matrices. This involves a data compression step where the measured absorbances are reduced to a small number of values called “scores” in a new coordinate system. The new axes are called “principal components” or “factors”. PLS assumes a linear relationship between the concentrations and scores. The regression coefficients from each original variable to each principal component are called “loadings”. Once the model has been fully developed, it can be used to determine analyte concentrations simply by using the data set for mixtures of unknown concentrations.
The effect of different variables (e.g., the influence of noise on both the analytical signal and the rate constants) on the quality of resolution of binary mixtures by PLS has also been assessed from simulated data, as has the potential of this algorithm for multicomponent kinetic determinations in nonlinear systems (e.g., in the presence of synergistic effects).\textsuperscript{(16)} In contrast to curve-fitting and Kalman filtering approaches, these MCMs require no prior knowledge of rate constants or absorbance coefficients and entail no explicit adoption of a given kinetic model. Regarding the rate constant ratio for mixture components, because the resolution of the mixture relies on both spectral and kinetic discrimination, even mixtures of more than two components with near-unity ratios can be resolved. However, the rate constant ratio has a great influence on the mixture resolution in the presence of synergistic effects (it must be higher than three), as shown by applying PLS to simulated data.\textsuperscript{(16)}

On the other hand, a procedure based on factor analysis was satisfactorily applied to kinetic data simulated from Gaussian and real spectra for Co(II) and Ni(II) using the above-mentioned ligand exchange reaction.\textsuperscript{(17)} Kalman filtering is a more effective approach when it is combined with spectral discrimination. Thus, the extended form of this algorithm has been fostered by combination with multiwavelength photometric determination, which is particularly effective for the simultaneous kinetic resolution of complex mixtures. Simulations have shown that mixtures can be successfully determined even if the rate constants of the two reactants are identical, as long as some spectral difference existed.\textsuperscript{(18)} Quencer and Crouch\textsuperscript{(19)} established the basis for the simultaneous determination of species from both their spectral and kinetic differences. Their approach allows resolution of more closely related species, thanks to the fast computation capabilities derived from the recursive nature of the Kalman filter. How large the differences need be to ensure accurate results depends on the number of wavelengths used for analysis; however, the larger the number of wavelengths used, the stronger is the overlap that can be tolerated. The accuracy of the determination is very good, even with a high degree of overlap and a few wavelengths; also, systems with completely overlapped kinetics can be resolved provided spectral differences exist at the chosen wavelength, and systems with completely overlapped spectra can be successfully determined as long as sufficient kinetic differences exist.\textsuperscript{(19)} In the latter case, rate constants must differ by a factor of about 2.5–3 for acceptable results to be achieved using the extended Kalman filter.

5.2 Kinetic Wavelength-pair and H-Point Methods

Although the principle of these methods is different, both have been developed for the ultraviolet–visible spectroscopic kinetic analysis of two-component systems involving the selection of one or two wavelength pairs.

The kinetic wavelength-pair or dual wavelength method\textsuperscript{(20)} involves measuring the difference in the rate of change of absorbance as a function of time at two preset wavelength pairs. The rate of change of absorbance, \( u = \Delta A / \Delta t \), is dependent on the wavelength used and should not be confused with the chemical reaction rate, which is the same at any wavelength for a given concentration. The aim of this method is to enhance the accuracy in simultaneous multicomponent resolutions by increasing the differences between the absorptivity coefficient ratios of the components in the mixture at the preset wavelengths. A diode array spectrophotometer and a computer furnished with suitable software are required for application of this method.

For a mixture of two components M and N, it application involves measuring \( u \) at two wavelength pairs, \( (\lambda_1, \lambda_2) \) and \( (\lambda_3, \lambda_4) \) (for simplicity subscripts 1–4 in the expressions below denote measurements made at \( \lambda_1-\lambda_4 \) respectively), which are chosen in such a way that the difference between the rates of change of the absorbance for the first wavelength pair is as large as possible for one of the components (e.g., N), and the opposite holds for the second wavelength pair. The data set thus obtained allows determination of the concentrations of M and N in the mixture by using a single aliquot. Hence, if additivity of the rates of absorbance change at each wavelength is fulfilled, Equation (19) follows:

\[
\begin{align*}
  u_i &= \left( \frac{\Delta A}{\Delta t} \right)_{M,i} + \left( \frac{\Delta A}{\Delta t} \right)_{N,i} \quad (19)
\end{align*}
\]

where \( i \) is the selected wavelength.

Taking into account the differences between wavelength pairs, the following systems of Equations (20) and (21) can be established:

\[
\begin{align*}
  u_2 - u_1 &= \left( \frac{\Delta A}{\Delta t} \right)_{M,2} + \left( \frac{\Delta A}{\Delta t} \right)_{N,2} \\
  &\quad - \left( \frac{\Delta A}{\Delta t} \right)_{M,1} - \left( \frac{\Delta A}{\Delta t} \right)_{N,1} \quad (20)
\end{align*}
\]

\[
\begin{align*}
  u_4 - u_3 &= \left( \frac{\Delta A}{\Delta t} \right)_{M,4} + \left( \frac{\Delta A}{\Delta t} \right)_{N,4} \\
  &\quad - \left( \frac{\Delta A}{\Delta t} \right)_{M,3} - \left( \frac{\Delta A}{\Delta t} \right)_{N,3} \quad (21)
\end{align*}
\]

where \( u_3 > u_1 \) and \( u_4 > u_3 \).

Parameter \( u \) is related to the chemical reaction rate, \( v \), through Equation (22) and (23):
where \( k_M \) and \( k_N \) are the first-order rate constants and a path length of 1 cm is assumed. A combination of Equations (20), (21), (22) and (23) yields Equations (24) and (25):

\[
\begin{align*}
\frac{u_{2-1}}{M} &= u_2 - u_1 = k_M (\varepsilon_{M,2} - \varepsilon_{M,1})[M] \\
&\quad + k_N (\varepsilon_{N,2} - \varepsilon_{N,1})[N] \\
\frac{u_{4-3}}{N} &= u_4 - u_3 = k_M (\varepsilon_{M,4} - \varepsilon_{M,3})[M] \\
&\quad + k_N (\varepsilon_{N,4} - \varepsilon_{N,3})[N]
\end{align*}
\]

which allows the concentrations of M and N to be simultaneously determined.

The four wavelengths used are selected and \( u \) calculated by computer. The conditions yielding the most accurate and sensitive estimate of M and N concentrations are those at which the differences between \((\varepsilon_{M,2} - \varepsilon_{M,1})/(\varepsilon_{N,2} - \varepsilon_{N,1})\) and \((\varepsilon_{M,4} - \varepsilon_{M,3})/(\varepsilon_{N,4} - \varepsilon_{N,3})\) are maximal and parameters \( u_2 - u_1 \) and \( u_4 - u_3 \) are as large as possible.

Considerable simplification is introduced when only one component contributes at each wavelength pair (e.g. \((\Delta A/\Delta t)_{N,2} = (\Delta A/\Delta t)_{N,1}\) and \((\Delta A/\Delta t)_{N,4} = (\Delta A/\Delta t)_{N,3}\)). In that case, Equations (24) and (25) become Equations (26) and (27):

\[
\begin{align*}
\frac{u_M}{M} &= u_2 - u_1 = k_M (\varepsilon_{M,2} - \varepsilon_{M,1})[M] \\
\frac{u_N}{N} &= u_4 - u_3 = k_N (\varepsilon_{N,4} - \varepsilon_{N,3})[N]
\end{align*}
\]

Hence \( u_M \) is independent of the concentration of N and \( u_N \) is independent of that of M.

The kinetic wavelength-pair method considerably enhances accuracy relative to some classical kinetic approaches (e.g. logarithmic extrapolation, single point and proportional equation methods), as shown in the simultaneous determination of formaldehyde and acrolein by reaction with 3-methylbenzodiazolin-2-one hydrazone.

There are some advantages associated with the use of the kinetic wavelength-pair method. Thus, the resolution is based on kinetic and spectral differences. Therefore, the simultaneous kinetic determination of species with rate constant ratios close to unity is possible whenever enough spectral differences exist. On the other hand, application of the method requires no use of complex chemometric procedures and, in principle, there are no restrictions with regard to the number of components that can be determined. Its main drawback is a low sensitivity compared with methods based on peak wavelengths. The method has also been extended to the fixed-time kinetic approach\(^{(21)}\) and has been applied to the resolution of binary mixtures of arsenate and phosphate,\(^{(21)}\) \(o\)-cresol and \(m\)-cresol,\(^{(22)}\) as well as to ternary mixtures of phenothiazines,\(^{(23)}\)

The \(H\)-point standard addition method (HPSAM)\(^{(24)}\) is identified for two cases, namely the determination of two species of which only one evolves with time, and that of two species with overlapped time evolutions.

For a mixture of two components \(C_1\) and \(C_2\), the determination of the concentration of \(C_1\) at equilibrium by the HPSAM entails selecting two wavelengths, \(\lambda_1\) and \(\lambda_2\), lying on each side of the absorption maximum of \(C_2\) so that the absorbance of the latter component is the same at both wavelengths. Then, known amounts of \(C_1\) are successively added to the mixture and the resulting absorbances at the two wavelengths are measured. The two straight lines thus obtained intersect at the so-called \(H\)-point \((-C_{1H}, A_{1H})\), where \(-C_{1H} = (\pm C_{C_2})\) is the unknown concentration of \(C_1\) and \(A_{1H} = (\pm A_{C_2})\) is the analytical signal of \(C_2\). When one of the species evolves with time, the variables to be fixed are two times, \(t_1\) and \(t_2\). Species \(C_2\), which should not evolve with time over this range, should have constant absorbance. This contrasts with the equilibrium HPSAM, where two wavelengths are chosen. A plot is then constructed of added \([C_1]\) on the \(y\)-axis and \(\Delta A\) for the two times on the \(x\)-axis. The point where \(\Delta A = 0\) is equal to \(-[C_1]\).

When both species evolve with time, \([C_1]\) can be calculated by plotting \(\Delta A\) for the two times against the added concentration of \(C_1\) at two wavelengths \(\lambda_1\) and \(\lambda_2\) provided the absorbances of \(C_2\) at these two wavelengths are the same.

5.3 Miscellaneous Methods

The continuous addition of reagent (CAR) technique\(^{(25)}\) is also applicable to multicomponent kinetic determinations. This method allows the resolution of mixtures of species basically thanks to the special way in which sample and reagents are mixed, discrimination being mainly of the instrumental type.

This method is based on the continuous addition of a reagent at a constant rate to the species to be determined.\(^{(25)}\) The model for this method was developed for a single component but has readily been extended to multiple reacting species. If a solution of a reagent \(R\) of concentration \([R]_0\) is added at a constant rate \(u\) to a volume \(V_0\) of a solution containing the analyte C, then the overall rate of the process will be given by Equation (28):
on the assumption that, under short reaction times, dilution of the analytes can be neglected. $k$ is the second-order reaction rate. Equation (28) is used to construct a linear calibration graph by plotting the initial slopes of the kinetic curves as a function of $[C]_0$ over a fixed time interval in all experiments.

Two or more kinetic curves corresponding to as many components are sequentially obtained by recording the changes in the analytical signal as function of time; the respective slopes are proportional to the individual concentration of each component. The reactions of mixtures whose components react very rapidly under pseudo first-order conditions are slowed on switching to pseudo second-order kinetic conditions, which allows the separation of the analytes on different timescales according to their reactivities and reaction rates. These reactions are independent of each other and are related to the characteristic parameters of the CAR technique shown above and to the concentration of each component through Equation (28), established from initial rate measurements. For a mixture of two components A and B these reaction rates are given by Equations (29) and (30)\(^26\)

\[
\frac{d[A]}{dt} = k_A \left( \frac{u[R]_0}{V_0} \right) t[A]_0 \quad (29)
\]

\[
\frac{d[B]}{dt} = k_B \left( \frac{u[R]_0}{V_0} \right) t[B]_0 \quad (30)
\]

If $k_A > k_B$, only component A will react with the reagent, R, added from the autoburette; once component A has almost completely reacted, the addition of a fresh volume of R starts the reaction of component B and the concentrations of A and B are calculated from Equations (29) and (30), respectively. This method involves no complex mathematical treatment and can also be used to resolve multicomponent mixtures by using $n$ equations in unknowns, provided appropriate values of adequate $k_{M}/k_{n-1}$, $k_{n-1}/k_{n-2}$ and so on can be obtained in order to minimize errors.

Mixtures of metal ions such as copper(II) and iron(III)\(^{26}\) and pesticides such as zineb and maneb\(^{27}\) have been resolved by using complex-formation reactions in both cases. Figure 4 shows the absorbance–time curve obtained for a mixture of zineb and maneb.

6 PHYSICOCHEMICAL DISCRIMINATION: MICellar CATALYSIS

Micellar catalysis can be a powerful tool for implementation of differential reaction rate methods. Micelles can alter the apparent rate constant ratio of two or more species that interact with a common reagent by both altering their intrinsic reactivity and, more generally, binding to a different extent to different analytes. According to the pseudophase model\(^{28}\) the observed second-order rate constant for a bimolecular reaction between A and B in the presence of micelles, $k_{exp}$, is given by Equation (31)

\[
k_{exp} = \frac{(k_{M}P_{A}P_{B} + k_{M}P_{A} + k_{M}P_{B})CV + k_{W}(1 - CV)}{(1 + K_{A}C)(1 + K_{B}C)}
\]

where the subscripts M, w, A and B denote quantities related to the micellar phase, aqueous phase and reactants, respectively; $P_{A}$ and $P_{B}$ are the partition coefficients of the reactants (i.e. $P_{A} = [A]_{M}/[A]_{w}$); $C$ is the surfactant concentration (molarity) minus the critical micelle concentration; $V$ is the molar volume of surfactant; the factors $CV$ and $(1 - CV)$ are the volume fractions of the micellar and aqueous phase, respectively; and $K_{A}$ and $K_{B}$ are the binding constants of the reactants, viz. $K_{A} = (P_{A} - 1)V$ and $K_{B} = (P_{B} - 1)V$; $k_{M}$ and $k_{W}$ denote the rate constants of the reactions taking place in the micellar and aqueous phase, respectively; $k_{M}^{*}$ is the rate constant of the reaction resulting from collisions between reactant A in the micellar phase and reactant B in the aqueous phase, and $k_{W}^{*}$ is the rate constant of the reaction between reactant B in the micellar phase and reactant A in the aqueous phase.

The efficiency of micellar catalysis, a parameter of interest in kinetic methodology, will be given by the ratio ($k_{exp}/k_{w}$), which depends on two factors, Equation (32):

\[
\frac{k_{exp}}{k_{w}} = \frac{k_{M}K_{A}P_{B}}{k_{w}V(\sqrt{K_{A}P_{B}} + \sqrt{K_{B}P_{A}})^2}
\]

The first factor ($k_{M}/k_{w}$) takes into account the changes in intrinsic reactivity when the reactants are transferred

![Absorbance–time curve provided by the CAR technique for a mixture containing 1.2 µg mL\(^{-1}\) zineb and maneb. (Reproduced by permission of the Royal Society of Chemistry, from Quintero et al.\(^{27}\))](image)
from water into the micelle phase and hence the specific effect of the micelles on the transition state of the reaction. The second factor depends on the effective reactant concentration in the micellar pseudophase and is dependent on the binding constants of the reactants to the micelles ($K_A$, $K_B$) and the molar volume of the surfactant ($V$). Analysis of different reactions developed in the presence of micelles in the light of different models showed that the observed increase in the reaction rate was mainly caused by the reactant concentrating in a low volume in the micellar pseudo-phase since the values of $k_M$ and $k_w$ were similar.

For two analytes with different partition coefficients, the ratio between their rate constants will depend on the surfactant concentration. As a result, micellar aggregates might be useful for the resolution of mixtures of species with similar reactivities in aqueous media or in those cases where a given component takes too long to react and thus precludes analytical measurements.

There are many other features of micellar aggregates that can be of great value in multicomponent kinetic analysis. Thus, micelles have been used to alter reaction pathways, modify the mechanisms through which these reactions develop and alter product distribution in reactions where two or more products are generated. Consequently, micelles can alter the physicochemical features of the reactant or product of the reaction concerned and give rise to spectral shifts, changes in molar absorbivity and so on, which make them firm candidates for kinetic multicomponent analysis.

Micellar catalysis has been applied to the determination of binary mixtures of cyanide, sulfide and sulfite based on their reaction with 5,5'-dithiobis(2-nitrobenzoic acid) (DTNB). The anion mixture could not be resolved by conventional differential kinetic analysis in an aqueous medium because of the similar reactivity of sulfide and sulfite ions and the slowness of the reaction between cyanide and DTNB, which took ca. 100 min to complete. The dependences obtained by plotting the observed rate constants, $k_{exp}$, of the reactions among the three ions and DTNB as a function of the cetyltrimethylammonium bromide (CTAB) concentrations (Figure 5) showed that, by selecting an appropriate concentration of surfactant, adequate differences between the rate constants were obtained and binary mixtures of the anions at micromolar concentrations could be resolved by using a multiple linear regression method.

Micellar control of reaction pathways leading to specific products can be of great use in multicomponent kinetic analysis. One representative example of the potential of this micellar effect is the simultaneous determination of V(V), Cr(VI) and Ti(IV) based on their reactions with pyrogallol red (PR) in the presence of dodecyltrimethylammonium bromide (DTAB) micelles. In an aqueous medium, PR is gradually decolorized by oxidation with chromium(VI) and vanadium(V), so the simultaneous resolution of these two ions is rendered impossible by their similar reactivity. Titanium(IV) interferes with the individual determinations of these ions by forming a complex with PR. DTAB micelles have the following effects on the process: they catalyze the oxidation of PR by Cr(VI); they allow the oxidation reaction between V(V) and PR to be completely displaced by a complex-formation reaction between the two species, and they also alter the photometric features of the Ti(IV)–PR complex. These changes allow the simultaneous resolution of the three ions from measurements made at three different wavelengths corresponding to as many reaction products. The linear determination ranges thus achieved are between 0.2 and 1 µg mL$^{-1}$ and the relative errors made in the resolution of the ternary mixture vary from 0.7 to 1.4%.

The use of micellar media can be a powerful tool for enhancing kinetic determinations and facilitating kinetic multicomponent analyses.
7 PRACTICAL IMPLEMENTATION: AUTOMATED METHODS

The conversion of differential kinetic methods of purely academic interest into practical methods for routine analysis entails a certain degree of automation. Electronic devices and computers have played a decisive role insofar as they have solved the problems associated with the measurement of time (i.e. especially in fast processes) by permitting automated acquisition of data during development of the process. Differential kinetic methods use instruments of varying degrees of complexity, from conventional elementary systems to sophisticated, completely automated instruments capable of collecting the sample, transporting it to the detector and processing the results obtained. This latter trend has been significantly fostered by the development of automated instrumentation for the computation of reaction rates such as the incorporation of SF mixing chambers into conventional photometric (including diode array) or fluorimetric detectors (for fluorescence or chemiluminescence measurements), the use of a simple automatic titrators and the implementation of continuous-flow techniques on simple manifolds, among others.\(^{2,4,31,32}\)

Kinetic measurements are free from effects of factors that introduce errors in absolute values (e.g. turbidity, the presence of other absorbing or fluorescent substances provided they do not take part in the reaction of interest or alter the parameter response); as a result they are based on temporal changes in the parameter used to monitor the reaction (absorbance, fluorescence, intensity, potential) rather than on their absolute values. However, strict timing and temperature control (to within 0.01–0.1°C) are essential for kinetic methods, which thus require modern powerful instrumentation. The choice of a given method for implementing rate measurements of a reaction is dictated by its half life. Thus, the instrumentation required to monitor slow reactions is typically simpler than that needed for fast reactions.

The process involved in measuring the rate of two or more components in a sample by using a common reagent comprises the following steps:

1. preparation, measurement, transport and mixing of reactants
2. signal monitoring and transducing at a constant temperature by measuring changes in a property of the reactants or products
3. timed acquisition of data (viz. collection of signals at different times) which are simultaneously or sequentially processed, usually with the aid of a computer.

Fully automated systems execute all three steps above, whereas partly automated instruments usually perform steps (2) and (3) only, and process data in a sequential rather than simultaneous manner.

In this section are briefly described currently available mixing modes and instrumental measurements such as flow techniques (low-pressure continuous and high-pressure SF techniques), used with single- or multi-wavelength photometric detection and luminescence detection, and the low-pressure CAR technique with photometric or luminescence detection, in addition to other approaches such as the T-optical fluorescence technique.

The increasing popularity of multicomponent kinetic methods is reflected in the variety of real analytical problems which are currently being addressed with their help.\(^{4,31}\)

7.1 Mixing Modes and Instrumental Assemblies

The first step in the kinetic process, that is the mixing of sample and reagents, is common to other analytical methods but is a key step in kinetic methods as it involves measuring the parameter via which the process is monitored. The way in which reactants are mixed to start the analytical reaction depends on whether the external experimental conditions will remain unchanged (closed systems) or not (open systems). Closed systems are unsuitable for fast reactions while open systems are specially suited to reactions with fast kinetics. The sample must be thoroughly mixed with the reagent(s) at a constant temperature before it is transferred to the detection system for measurement. This can be done manually, which is usually the case with closed systems, or automatically. Manual mixing can be accomplished simply by homogenizing the reactants in the reaction vessel, which can be a spectrophotometric cuvette or an electrode cell. The instant at which the last reactant is added is taken as the reaction start time \(t = 0\) and must therefore be determined with great accuracy.

Automated mixing of sample and reagents calls for special mechanical/electronic devices when fast reactions, which as noted earlier require the use of open systems, are addressed. This increases the reproducibility and throughput of multicomponent kinetic analysis and is the reason why automated open systems are preferable even when slow reactions are involved.

The most frequently used open systems can be classified into continuous or flow systems and discrete systems. The most popular and widely employed techniques in connection with such systems for multicomponent kinetic determinations in routine analyses are flow injection and SF among the former and the CAR technique among discrete systems.
As a rule, the flow rate of the sample and/or reagents in the mixing system can be zero or constant while the kinetic curve is being recorded. The former alternative is the basis for SF systems; on the other hand, in continuous addition analyses, the flow rate of one of the reaction ingredients is nonzero and constant. Throughout the measurement interval, the reactants can be circulated at a given identical flow rate in flow injection analyses.

SF is highly versatile and often superior to other flow techniques such as continuous-flow analysis (CFA), both in its air-segmented CFA and in its unsegmented mode (flow-injection analysis, FIA). Thus, SF can be applied to the resolution of mixtures following very fast kinetics with higher sample throughput and lower reagent consumption than those afforded by FIA or CFA.

The choice of a given technique will be dictated not only by its technical features, but also by the half lives of the reactions concerned as shown below.

7.2 High-pressure Stopped-flow Technique

This technique is the most commonly used for the resolution of mixtures involving fast reactions (namely those with half lives of a few milliseconds to a few seconds). In conventional SF systems, the sample and reagents are mixed at high pressure by means of two driving syringes that are actuated manually or automatically (e.g. by pneumatic device) which are inserted into a flow cell or mixing chamber that can also act as the observation cell. The flow is then abruptly stopped by using a third syringe and the analytical signal is recorded as a function of time. The system can be controlled by computer which can also be used for data acquisition and processing. The dead time of the instrument, which is determined by the mixing efficiency (viz. the mixing time) and the transport and stop times, must be smaller than the half life of the reaction of interest by about two orders of magnitude. The high cost of SF instruments (which has delayed its use in routine analyses) can be avoided by using commercially available SF mixing modules to fit to conventional and diode array photometric, fluorimetric and chemiluminescence detectors for implementation of the SF techniques. Figure 6 depicts a SF mixing module controlled by a simple computer interfaced on-line to it. The module is accommodated vertically above the detector. This modular SF system is applicable to reactions with half lives in the millisecond range. Analytical results are rapidly obtained by using computer software for differential kinetic methods, this ensures high sample throughput, reproducibility and accuracy. The modular system has proved fairly efficient in the spectrophotometric or spectrofluorimetric determination of binary mixtures of metal ions, biogenic amines, drugs and pesticides. Some of the ensuring methods are based on slow reactions, which also benefit from the simplicity, rapidity, precision and minimum sample and reagent manipulation of the SF technique.

The above-described SF module was also incorporated into a commercial diode array spectrophotometer to resolve multicomponent mixtures by kinetic methodology. The ability to make absorbance measurements as a simultaneous function of time and wavelength is a powerful way of accomplishing kinetic multicomponent analyses, as shown in section 5. Two or more reactions involving the same or different reagents can be simultaneously monitored in this way. When the absorption spectra for the mixture components are sufficiently resolved (i.e. in the simplest case), kinetic data can be readily obtained at each absorption maximum without the need to apply differential kinetic methods based on mathematical approaches, provided the reaction rates of the components are independent of one another. Figure 7 shows the three-dimensional plot for a mixture of hydrazine and phenylhydrazine determined by their corresponding condensation reactions with p-dimethylaminobenzaldehyde (DAB), as well as their respective kinetic curves, which were computed simultaneously. These data allowed the individual and/or simultaneous determination of these compounds by applying a computerized initial-rate method.

SF differential rate methods have also been applied to energy-transfer sensitized luminescence reactions based on the energy transfer from an excited organic compound analyte to europium or terbium ion which gives a characteristic line-type emission at 612 nm [Eu(III)] or 545 nm

Figure 6 Schematic diagram of a modular SF system. A, Driving and stopping syringes; B, mixing-observation chamber; C, pneumatic propulsion system; D, thermostatted chamber. (Reproduced by permission of the Royal Society of Chemistry, from Pérez-Bendito.)
[Tb(III)]. These methods rely on the different rates of formation of a lanthanide–analyte–ligand ternary complex in the presence of a surfactant, which is very fast and require the use of the SF technique. Tetra-cycline–doxycyclines in mixtures were simultaneously determined in this way, in untreated serum samples using the proportional equation method. The kinetic curves were obtained by placing Eu(III) and thenoyltrifluoroacetone (TTA) in one of the syringes and tetracycline plus Triton X-100 in the other. A similar approach was also developed for the simultaneous determination of salicylic acid and diflunisal with terbium(III)–EDTA (N,N,N0,N0-ethylenediaminetetraacetic acid) and CTAB in a basic medium.

7.3 Low-pressure Continuous Flow Techniques

The unsegmented continuous-flow technique, so also called “FIA” is one other automated approach for implementing the differential reaction rate method. Although it is unsuitable for fast reactions (mixing is not efficient enough owing to the low pressure in the merging streams and dispersion decreases the sensitivity) it has been used in multicomponent kinetic determinations by virtue of the very simple instrumental set-up required. Typically, this consists of a peristaltic pump for propelling a carrier, into which the sample is injected by means of an injection valve, and one or more reagent streams that merge at a mixing point and then pass through a reaction coil of appropriate length before they reach a flow-cell placed in the detector. The analytical signal is a sharp peak the height of which is directly related to the analyte concentration. The degree of complexity of this configuration depends on whether it includes one or several detectors, simple or multiple injection, whether or not it involves splitting or stopping the flow and so on.

Flow-injection differential reaction rate methods are essentially based on the formation of two reaction zones reacting in the detector at different times, the use of multiple detection points separated by delay coils or the iterative passage of the reacting plug by the same detection point. Depending on the type of data obtained, there are two basic types of flow-injection differential reaction-rate methods, that is those based on two signals measured at different reaction times and those relying on multipoint signal–time curves. From a practical point of view, the most outstanding differential reaction-rate methods implemented in simple flow manifolds rely on the formation of two reaction zones based on the differential contribution of each analyte to each peak resulting from differences in reaction rate. The mixture is resolved by applying the classical proportional equation method (section 3.1). One example is the analysis of mixtures of cobalt and nickel based on the formation of their complexes with 2-hydroxybenzaldehyde thiosemicarbazone.

The other type of method involves the iterative passage of the reacting plug through a nondestructive detector in order to obtain multiplex recordings that can be used for kinetic purposes since the envelopes of their maxima and minima resemble typical kinetic curves.
7.4 Low-pressure Continuous Addition of Reagent Technique

The special way in which the sample and reagents are mixed in this technique affords the resolution of mixtures by direct kinetic methods. The description and theoretical formulation of this technique are given in section 5.3. The experimental set-up for implementation of the CAR technique is shown in Figure 8. A typical CAR assembly consists of (1) an addition unit composed of an autoburette, a magnetic stirrer and a thermostatted vessel as reaction cell, (2) a photometric/fluorimetric or chemiluminescence detection unit that can includes an immersion probe for photometric measurements and (3) a computer. The reaction vessel can be of variable capacity from 60 mL to about 2 mL and typically holds sample volumes in the microliter range. This makes the technique especially useful when the amount of sample available is limited (e.g. with serum samples).

The CAR technique is a major alternative to the SF technique in tackling direct rate measurements of reactions with half lives of a few milliseconds, each component of the mixture is determined in a sequential manner in a single run of sample. Typical examples are the photometric determination of binary mixtures of carbamate pesticides (see Figure 4) in commercial formulations, and of copper and iron in serum samples by use of a miniaturized reaction chamber and photometric detection.

The CAR technique has also been used for the resolution of mixtures involving chemiluminescent reactions by using peroxyoxalate energy-transfer processes. 2,4-Trichlorophenylperoxyoxalate (TCPO) was added from the autoburette to the sample (a mixture of trimeprazine and methotrimeprazine) in excess hydrogen peroxide in the reaction vessel. A single kinetic curve (sum of the two reactions) was obtained and the kinetometric ANN approach (see section 4.3) was used to resolve the mixture, the components of which exhibited a similar kinetic behavior and synergism. The CAR technique suppresses the background emission associated with this type of chemiluminescence reaction, thereby increasing the signal-to-noise ratio.

7.5 Miscellaneous Instrumental Approaches

Kinetic fluorimetric methods for the simultaneous resolution of mixtures usually involve chemical reactions that must meet several requirements when a conventional L-format spectrofluorimeter is used, namely: (1) similar maximum excitation and emission wavelengths for their reaction products and (2) differential kinetic behavior. In addition, if the reaction rate of any of the systems involved is very fast, the reactants cannot be mixed manually batchwise since the reaction is finished by the time the instrument starts acquiring the kinetic curve. However, the use of a spectrofluorimeter in a T-format configuration (one with two emission paths symmetrically arranged on both sides of the sample compartment), which is commercially available, allows two chemical systems with similar excitation wavelengths but different emission wavelengths to be monitored. The absence of overlap in the emission maxima allows kinetic data to be obtained from each individual system, even if both possess similar rate constants.

When the chemical system involves fast reactions, the combined use of one such spectrofluorimeter with the SF technique allows kinetic data to be obtained and provides a means for automation and rapid handling of reagents, both of which are highly desirable in routine analyses. Figure 9 shows a scheme of this approach, which provides “instrumental discrimination” for the resolution of neomycin and promethazine using two different reactions, namely o-phthaldialdehyde (OPA) in the presence of N-acetylcysteine to yield a fluorescent substituted isoindole by its condensation with neomycin and the oxidation of promethazine to a fluorescent sulfoxide by dissolved oxygen. The sample solution, in a borate buffer medium, was placed in one of the syringes, the other being filled with an aqueous solution containing OPA, N-acetylcysteine and borate buffer. The common excitation wavelength used was 335 nm; the oxidation of promethazine was monitored on channel B at 370 nm and the condensation of neomycin on channel A at 460 nm. The respective kinetic data were processed by a microcomputer and the initial rate method was used to determine each component in the mixture.
Differential Rate Determinations

The introduction of the analyte pulse perturbation (APP) technique\(^{(42)}\) has opened up new prospects for differential rate determinations based on oscillatory reactions, which are a special type of far-from-equilibrium dynamic system. This technique allows the steady state of an oscillating reaction to be rapidly restored after each perturbation with a microvolume of the analyte added to a continuous-flow stirred tank reactor (CSTR); this affords many determinations on the same oscillating system in a simple rapid manner. Thus, two or more different responses corresponding to as many components are sequentially obtained in the oscillating system; the respective perturbation (i.e. change in period or signal amplitude of the oscillating curves) is proportional to the individual concentration of each component.\(^{(43)}\) This approach is very simple since it requires none of the complex mathematical treatments used in kinetometric approaches. Figure 10 shows a schematic depiction of the experimental set-up required for the resolution of gallic acid/resorcinol mixtures\(^{(43)}\) based on their perturbation (Figure 11) on the copper(II)-catalyzed oscillating reaction between hydrogen peroxide and sodium thiocyanate, using the

APP technique as implemented in a thermostatted CSTR, potentiometric detection, a peristaltic pump to dispense the reagent continuously and keep the volume in the CSTR constant, and a computer to acquire and process data.

8 MULTICOMPONENT KINETIC DETERMINATIONS AS PROBLEM SOLVERS

One of the best indicators of the consolidation of differential reaction-rate methods is their increasing use for solving real problems.\(^2^4\)

Thus speciation has also been addressed by using these methods. Distinguishing between the forms (free or bound) or oxidation states in which a given species can occur in a sample is possible by applying differential rate methods. Fe(III) and Fe(II) can be simultaneously determined in iron-rich groundwater through the aerial oxidation of Fe(II) in the presence of Tiron and acetate ion; the Fe(III) formed is subsequently complexed with Tiron and the reaction is monitored spectrophotometrically. The concentrations of Fe(III) and Fe(II) are obtained from the initial and equilibrium absorbance values, respectively, which are calculated by nonlinear least-squares fitting (without the need for any prior rate constant measurement).\(^44\) The same iron ions were determined in wines by the formation of the Fe(III)–thiocyanate complex, using the SF technique to process the two samples needed for analysis.\(^33\) In the speciation of Sb(III) and Sb(V), the differential rate of reaction of the two ions with mandelic acid enabled their discrimination.\(^45\) The different forms in which a metal ion can occur in a given medium such as water or soil (e.g. free, complexed or bound to organic molecules) can be discriminated by adapting conventional differential reaction-rate methods to the analysis of mixtures for which neither the number of components nor their rate constants is known. Such is the case with the kinetic speciation of Ni(II) bound to fulvic acid in a soil.\(^46\)

Differential kinetic analyses have also proved useful in various analytical areas of interest such as environmental and clinical chemistry for the determination of organic and inorganic species in mixtures. Mixtures of carbamate pesticides (e.g. carbaryl + 1-naphthol, carbaryl + 1-naphthol + 2-naphthol and carbofuran + propoxur) in different types of water samples were resolved with satisfactory results by the SF technique.\(^44\) The micellar catalysis approach described in section 6 was also applied to the simultaneous kinetic determination of arsenate and phosphate in water samples.\(^47\) Mixtures of epinephrine and norepinephrine in urine\(^48\) were resolved by the automatic method described in section 7.2. Mixtures of phenothiazines in human serum samples,\(^23\) and o-cresol and m-cresol in urine samples,\(^22\) were resolved based on their respective oxidative coupling reactions, which exhibit strong kinetic and spectral overlap, using the kinetic wavelength pair-method described in section 5.2. These are but a few examples of the uses of differential rate methods with clinical samples that involve little or no sample treatment.

Pharmaceutical analysis has also benefited from differential rate methods.\(^49\) Thus, psychotropic drugs such as epinephrine and norepinephrine, chlorpromazine and perphenazine, and thiamine and cocarboxylase, among others, have been determined in different pharmaceutical preparations by using (mainly) proportional equation methods. Differential rate methods have also been applied to food analysis. Thus, the simultaneous determination of ampicillin and tetracycline in milk\(^50\) was accomplished by using the SF/T-format spectrophotofluorimeter described in section 7.5, as was the resolution of mixtures of the antioxidants butylated hydroxyanisole and propyl gallocate in commercial food samples (chicken and vegetable group, corn, sunflower, olive oils, and margarine) using SF diode array detection.\(^51\)

Most of these methods feature high sampling rates and have been promoted by the inception of the above-described automatic techniques. The expeditiousness with which samples can be processed and the ease with which the data produced can be treated have helped popularize multicomponent analytes by differential rate methods.

KINETIC DETERMINATIONS

50. B. Gala, A. Gómez-Hens, D. Pérez-Bendito, ‘Simultaneous Determinations of Ampicillin and Tetracycline in...

The term “electrocatalysis” denotes the catalysis of an electrochemical reaction. In accord with the general definition of catalysis(1) the effect of an electrocatalyst is to increase the rate of an electrochemical reaction without modifying the overall standard Gibbs energy change in the reaction. Taking the view of Faraday’s law, the rate of an electrochemical reaction is expressed by the electrolytic current. Consequently, an increase in the electrolytic current is the main result of electrocatalysis. The benefits of electrocatalysis include making possible the quantitation of the catalyst itself or of some substrate compounds that are not electrochemically active or are not generally amenable to direct electrochemical determination. An appreciable improvement in selectivity may be brought about by electrocatalysis. Additionally, appropriate engineering of catalytic layers on electrode surfaces has led to the preparation of a huge variety of chemical and biochemical sensors. However, close control of the experimental conditions (temperature, electrolyte composition) is often required when dealing with electrocatalytic processes. Usually, such requirements do not give rise to any particular difficulties.

1 INTRODUCTION

In contrast to conventional chemical reactions, the activation energy of an electrochemical reaction depends not only on the molecular/chemical factors (included in the so-called thermal term) but also on the electrode potential. That is why the rate constants for electrochemical reactions are exponential functions of the electrode potential. For the most simple electrochemical reaction (Equation 1)

\[ \text{Ox} + e \rightleftharpoons \text{Red} \]  

the current–potential relationship is expressed by the Butler–Volmer relationship (Equation 2):

\[ i = i_0 \left\{ \exp \left( \frac{-\alpha F\eta}{RT} \right) - \exp \left( \frac{(1-\alpha)F\eta}{RT} \right) \right\} \]  

where \( i_0 \) is the exchange current, \( \alpha \) is the transfer coefficient (\( \alpha \leq 1 \)), \( F \) is the Faraday constant, \( T \) is the absolute temperature and \( R \) is the gas constant. \( \eta \) denotes the overvoltage, i.e. the deviation of the actual electrode potential \( E \) from the equilibrium value \( E_e \) (Equation 3):

\[ \eta = E - E_e \]  

The expression for the exchange current (Equation 4) includes the standard rate constant for the electrode reaction, \( k_s \)

\[ i_0 = FAK_s c_{\text{Ox}}^{(1-\alpha)} c_{\text{Red}}^\alpha \]
where \( A \) is electrode area, and \( c_{\text{ox}}, \) and \( c_{\text{red}} \) stand for the bulk (equilibrium) concentrations. According to Equation (2), the absolute value of the current rises exponentially with the increase in the absolute value of the overvoltage. In practise, a nonelectrochemical step always limits the current increase to a value that is termed the limiting current. Under such circumstances, the rate-determining step can be either the transport of the reactant towards the electrode surface or a chemical reaction producing the electrochemically active species. In the last case, the term “kinetic current” is used to denote this special type of limiting current.

The effect of electrocatalysis is an increase in the standard rate constant, \( k_s \), which is followed by a rise in current value at a constant overvoltage. Because this effect can be masked by the intervention of a nonelectrochemical rate-determining step, the most straightforward mark of electrocatalysis is the shift of the electrode process to a lower overvoltage (in absolute value).

An electrochemical reaction, involving the electron transfer between two different phases, is intrinsically a heterogeneous process. However, electrocatalysis can be either heterogeneous or homogeneous in character. In the first case, the catalyst is confined to the electrode surface by adsorption, chemical bonding, adhesion or some other immobilization procedure. In the second case, the catalyst is present in the bulk of the solution and interface processes do not influence the chemical steps that involve it. A much more detailed approach of the general theory of electrocatalysis is available in the literature, with emphasis on technological applications. Some monographs on kinetic methods of analysis also include sections on electrocatalysis applications in electroanalytical chemistry. This topic is periodically surveyed in reviews published by the Journal Analytical Chemistry, jointly with either Kinetic Methods of Analysis or Electroanalytical Chemistry.

### 2 ELECTROCATALYSIS AT BARE ELECTRODES

A characteristic feature of bare-electrode processes is the occurrence of both the catalyst and the substrate in the bulk solution. Consequently, the process involves mass transfer processes for both. According to the nature of the catalyst-involving step, three kinds of electrocatalytic processes at bare electrodes can be distinguished: redox-type catalytic processes (mediated electron transfer), processes with proton transfer as a regenerative step (catalytic hydrogen evolution), and processes with a complex-forming regenerative step (catalytic reduction of some metal ions). Most of the research in this field has been done with mercury electrodes using either polarography or voltammetry at a stationary electrode, which is why the following discussion relates mostly to reduction-based processes. However, the conclusions can be easily transposed to anodic reactions.

#### 2.1 Redox-type Catalytic Processes

**2.1.1 Reaction Mechanism and Theoretical Approach**

A general reaction scheme for redox-type catalytic processes can be formulated as Equations (5–8), shown in Scheme 1.

\[
P + e^- \rightarrow O \\
O + A \xrightarrow{k_1} B + P \\
B \xrightarrow{k_2} C \\
A + e^- \rightarrow B
\]

**Scheme 1**

The couple P/Q plays here the role of an electron carrier from the electrode to the substrate A via Equations (5) and (6). The term “mediator” is frequently used to denote the couple P/Q or one of its members. Equation (6) represents the regeneration step involving the substrate A, leading to the reformation of the direct electron acceptor, P. In principle, the direct electrochemical conversion of the substrate (Equation 8) is also possible. However, a prerequisite for the catalytic process is the occurrence of this reaction at a more negative potential than that of Equation (5). The couple A/B must be a more powerful oxidant than P/Q (i.e. \( E_{A/B}^0 > E_{P/Q}^0 \)), but Equation (8) occurs with a high activation energy (i.e. high overvoltage) and is shifted to potentials much more negative than its standard potential. The electrolytic current for the above mechanism is known as the catalytic current. The term “parallel reaction” is often used for Equation (6), with Equation (5) being the main step. An electrochemical reaction with a parallel chemical regeneration (EC) is distinct from an electrochemical reaction with a subsequent chemical reaction (EC; i.e. with no regeneration). The subscripts “r” or “ir” attached to either E or C indicate the reversible or irreversible character of Equations (5) and (6), respectively. From the kinetic standpoint, the reversible or nernstian behavior of Equation (5) is defined by the condition \( k_s \rightarrow \infty \) (where \( k_s \) is the standard rate constant for Equation 5) whereas an irreversible character corresponds to a low value of \( k_s \). In thermodynamic terms, the nernstian character of
the reaction means that the Nernst equation relative to interface concentrations of both P and Q is fulfilled. The occurrence of Equation (7) is usually neglected.

A typical example of a redox-type catalyzed process is the reduction of Fe$^{3+}$ in the presence of hydrogen peroxide\(^{6,7}\) (Figure 1). In this case, the substrate is H$_2$O$_2$, whereas the couple Fe$^{3+}$/Fe$^{2+}$ plays the role of the electron carrier, P/Q, according to Equations (9) and (10):

$$\text{Fe}^{3+} + e^{-} \rightarrow \text{Fe}^{2+} \quad (9)$$

$$2\text{Fe}^{2+} + \text{H}_2\text{O}_2 + 2\text{H}^+ \rightarrow \text{Fe}^{3+} + 2\text{H}_2\text{O} \quad (10)$$

The main analytical application of this kind of electrode process is the analytical determination of P with an enhanced sensitivity due to the regeneration step (Equation 6). Accordingly, an increase in the reduction current of P occurs at the expense of the substrate A.

The theoretical approach aims at establishing the relationship between the limiting current on one side and the rate constant and reactant concentrations on the other side. A time parameter is always included in the kinetic equation, because of the dynamic character of the electrode process.

Most of the available theoretical treatments assume that the substrate is present in a high excess as compared with the mediator (so that Equation 6 is pseudomonomolecular) and Q is not initially present in the solution. Substrate excess is favorable from the standpoint of the analytical determination of P because maximum sensitivity is thus achieved. In addition, it is assumed that Equation (6) occurs by outer-sphere electron transfer and, consequently, does not involve the formation of an intermediate adduct. Adsorption of the compounds involved in the electrode process brings about some complications and is usually neglected. Under these circumstances Equation (6) occurs in a solution layer (the reaction layer) adjacent to the electrode surface. Under such ideal conditions, the regeneration step is a homogeneous reaction, with no effects from the electrode–solution interface. Equation (7) is assumed to be very fast and to have no kinetic relevance. These assumptions should be carefully considered when doing kinetic investigations, but are generally not critical from the standpoint of analytical applications.

Theoretical treatments for the above mechanism have been developed for various electrochemical methods and are amply reviewed.\(^6\)–\(^13\) The following discussion is confined to electrochemical methods currently used in chemical analysis. However, such methods also provide valuable tools for the kinetic investigation of any chemical reaction that may occur as a regeneration step in a catalytic electrode process. In addition, this kind of investigation can provide useful information for selecting an appropriate mediator when developing chemically modified electrodes (CMEs) with electrocatalytic properties (sections 3 and 4).

Generally, two kinds of theoretical approach may be used when dealing with any class of electrode process coupled with chemical reactions.\(^6\)–\(^9\) The rigorous approach proceeds by solving the mass-transfer differential equations that include some additional terms corresponding to the formation or elimination of the reactants (e.g. P, Q, and A) by the chemical reactions. For simplicity, it is often assumed that the diffusion coefficients have the same value for all the species involved. Although only numerical solutions for such equations are available, under limiting conditions it is still possible to obtain an analytical expression for the current as a function of the rate constant, reactant concentrations, and a time-parameter characteristic for each particular electrochemical method.

The more simple, but approximate, approach is based on the concept of the reaction layer. This is the solution layer adjacent to the electrode surface, where the equilibrium of Equation (6) is disturbed by the occurrence of Equation (5). If the regeneration rate is very fast, the diffusion of P may be neglected and the single species taking part in the diffusion process is A. Furthermore, it is assumed that the thickness of the reaction layer is very small compared to the thickness of the diffusion layer for A. Consequently the concentration of A inside the reaction layer is assumed to be constant. In addition,
it is supposed that the steady state occurs within the reaction layer, i.e. the formation of \( P \) by Equation (6) is completely balanced by its removal via Equation (5). Hence, the reaction layer method is restricted to the limiting case of a very fast parallel chemical reaction.

An alternative to the above methods is the digital simulation of the electrode process.\(^{14}\) The mass transfer model is discretized into events that occur within small time increments and small intervals of distance from the electrode surface. In this way, the concentration versus distance profiles can be calculated by successive iterations. Initial assumptions about the mechanism and the rate parameters must be made, and this makes unavoidable the use of the diagnostic criteria and relevant relationships derived by the previous methods. However, digital simulation is very useful when checking the validity of some approximations or for investigating complicated processes that cannot be handled by solving the relevant set of differential equations.

### 2.1.2 Kinetic Equations

#### 2.1.2.1 Direct Current Polarography

Most of the pioneering work in the field of catalytic electrode processes was done by the Czech school of polarography and is amply reviewed elsewhere.\(^{6-11,13}\) As a rule, the effect of sphericity is neglected and the dropping mercury electrode is regarded as an expanding plane electrode. This common approximation is valid provided that the thickness of the diffusion layer is much smaller than the electrode radius.

Taking into account the restrictions mentioned in the previous section, the solution to the system of differential equations for the diffusion of \( P \) and \( Q \), accompanied by the previous section, the solution to the system of differential equations.

The mass transfer of the electrode radius.

This common approximation is valid provided that the thickness of the diffusion layer is much smaller than the electrode radius.

The mass transfer of the electrode radius.

Accordingly, the catalytic wave is described by the well-known equation of the polarographic wave (Equation 14):

\[
i = \frac{i_c}{1 + \exp[aF(E - E_{1/2})/RT]}
\]

where \( i \) is the current as a function of electrode potential \( E \), \( n \) is the stoichiometric coefficient of the electron in the electrode reaction (Equation 5) and \( E_{1/2} \) is the half-wave potential. For the case of a reversible electrode reaction \( E_{1/2} = E_{0/2}^{\Psi} \) and \( \alpha = 1 \). For the opposite case of an irreversible electrode reaction, under the limiting conditions of a very fast parallel reaction \( \chi_1 > 10 \), \( E_{1/2} \) is dependent on both \( k \) and the rate constant \( k_1 \) (Equation 15):

\[
E_{1/2} = E^0 + \left( \frac{RT}{aF} \right) \ln \frac{k_s}{(D_P k_1 c_A^0)^{1/2}}
\]

where \( D_p \) is the diffusion coefficient of \( P \). The above relationships appear as particular cases of a more general treatment which is not restricted to the steady-state assumption and refers to an electrode expanding with any power law.\(^{16}\) Because most of the available theoretical treatments deal with the expanding plane electrode, the effect of electrode sphericity has been assessed\(^{17}\) and it was concluded that \( i_c \) is more affected than \( E_{1/2} \) by this approximation; however, only slight corrections are required.

If the regeneration step (Equation 6) is a second-order reaction, a subunitary correction factor should be added to Equation (13).\(^{6}\) This obviously brings about a decrease in the sensitivity of the determination of \( P \).

DC polarography provides some straightforward diagnostic tests for the occurrence of the catalytic electrode process. The most typical case is that corresponding to Equation (13). This implies a very fast regeneration of \( P \) and no concentration gradients for \( A \) (which is present in a high excess) or \( P \) and \( Q \) (which are cycled inside the reaction layer). Consequently, the overall electrode process is independent of mass-transport phenomena.\(^{6}\) Experimentally this is proved by the independence of the limiting catalytic current, \( i_c \), on the mercury pressure above the mercury electrode (expressed by the height of the mercury level above the lower end of the capillary
Electrode, \( n \) (Figure 1). This contrasts the behavior of the diffusion current, which is directly proportional to \( h^{1/2} \). Under intermediate conditions, the \( i_c \) versus \( h^{1/2} \) plot gives a straight line with a nonzero intercept. The investigation of the deuterium isotope effect is a valuable test for detecting the participation of hydrogen species in the rate-determining chemical step.\(^{18}\)

2.1.2.2 Linear Sweep Voltammetry and Cyclic Voltammetry at Stationary Electrodes Linear sweep voltammetry (LSV) is an essentially nonsteady-state method under convection-free conditions, involving a potential scan according to Equation (16):

\[
E = E_i + vt
\]

(16)

where \( E_i \) is the initial potential, \( v \) is the scan rate (in \( \text{V s}^{-1} \)), and \( t \) is the time variable. The output is the current–potential curve (known as a voltammogram) which displays asymmetric peaks corresponding to each electrode reaction. Cyclic voltammetry (CV) involves potential cycling with constant speed between two potential values. This makes it possible to detect the product of the initial scan from the relevant peak recorded during the reverse process.

The theory of the catalytic process in LSV, as worked out by Savéant and Vianello\(^{19}\) and Nicholson and Shain,\(^{20}\) is amply described elsewhere.\(^{11–13}\) It is assumed that \( c_A^{0} \gg c_p^{0} \) and \( k_2 = 0 \), so that Equation (6) is pseudomonomolecular and irreversible. The perturbation of the system is expressed by the dimensionless sweep rate \( a = nFv/RT \), whereas the mobility of the chemical reaction is shown by the pseudomonomolecular rate constant \( k_1c_A^{0} \). The treatment assumes a planar electrode (i.e. semi-infinite planar diffusion) but the results are reasonably correct for spherical electrodes as well. This is because the relevant processes occur in the reaction layer, which has a thickness much lower than the electrode radius.

The general solution of the differential equations for the mass transfer accompanied by the chemical reaction gives the current–potential relationship in the form of a series. First, the case of the reversible electrode reaction is considered (i.e. \( E = E_{P/Q}^{0} + (RT/nF) \ln(c_{P,i}/c_{Q,i}) \); the subscript \( i \) denotes concentrations at the electrode/solution interface). If the regeneration is very fast (\( k_1c_A^{0}/a \gg 1 \)), the current–potential curve assumes the shape of the steady-state voltammetric wave and is described by Equation (14) where \( a = 1 \) and \( E_{1/2} \) is the polarographic half-wave potential for the electron transfer reaction (Equation 5) (i.e. \( E_{1/2} = E_{P/Q}^{0} - (RT/2nF) \ln(D_P/D_Q) \); usually, \( E_{1/2} \approx E_{P/Q}^{0} \) because \( D_P \approx D_Q \)). Under these conditions, the value of \( i_c \) is dictated by the rate of the parallel reaction, according to Equation (17):

\[
i_c = nFAc_A^{0}(D_Pk_1c_A^{0})^{1/2}
\]

(17)

Accordingly, \( i_c \) is not dependent on the scan speed, in contrast with the peak current for the diffusion-controlled process, \( i_P \), which is recorded in the absence of \( A \) and is directly proportional to \( v^{1/2} \). This is an important diagnostic test for the catalytic process, in addition to the curve shape and the absence of the hysteresis on a CV run (provided that the reversal potential is not more negative than \( (E_{1/2} + 35/n) \text{mV} \)). Equation (17) enables a straightforward determination of the rate constant \( k_1 \).

The current amplification brought about by the regeneration of the electron acceptor is defined in Equation (18):

\[
\frac{i_c}{i_d} = 2.242\left(k_1c_A^{0}\right)^{1/2}a^{-1/2}
\]

(18)

At a very high scan speed (\( k_1c_A^{0}/a \ll 1 \)) the effect of the regeneration becomes less evident and the shape of the voltammetric pattern becomes an asymmetric peak. At the limit, the timescale is so short that Equation (6) is not disturbed any longer and the rate-determining step is the diffusion of \( P \).

If Equation (6) is reversible, both \( k_1 \) and \( k_2 \) must be taken into account and the limiting current recorded at a low sweep rate (\( k_1c_A^{0}/a \gg 1 \)) is given by Equation (19):\(^{11,21}\)

\[
i_c = nFAc_A^{0}[D_P(k_1c_A^{0} + k_2)]^{1/2}
\]

(19)

In the case of the irreversible electrode reaction the rate of Equation (5) is expressed by the Butler–Volmer equation and the dimensionless sweep rate is defined as \( b = anF/RT \). The current–voltage relationship is available as a series.\(^{11,20}\) However, for the analytically important case of a very fast regeneration (\( k_1c_A^{0}/b \gg 1 \)), the current–voltage relationship is in accord with Equation (14), i.e. it has a sigmoid shape with a limiting current \( i_c \) as given by Equation (17). The effect of irreversibility is demonstrated by the shape of the curve, which is more spread out than in the case of the reversible reaction (because \( a < 1 \)), and by the dependence of \( E_{1/2} \) on the rate constants for Equations (5) and (6).

The LSV technique has limited analytical applications but it is a very valuable tool for investigating catalytic electrode processes of analytical interest, involving either synthetic or biogenic catalysts.

2.1.2.3 Differential Pulse Polarography, Square-wave Voltammetry, and Alternating Current Polarography The above methods are characterized by the superposition of a periodic, small amplitude voltage (10–100 mV)
over the constant polarization potential. The superimposed signal is either square shaped (for differential pulse polarography (DPP) and square-wave voltammetry (SWV)) or is a sine wave (for alternating current (AC) polarography). An outstanding sensitivity is achieved owing to the ability of such methods to distinguish the electrolytic current (which bears the analytical information) from the disturbing capacity current. Additional improvement in the sensitivity and the detection limit is brought about by coupling the electrode reaction (Equation 5) with the chemical regeneration step (Equation 6).

In the case of DPP\(^{11,25}\) an amplification factor of \((\pi\tau k_i c_0^A)^{1/2}\) results from the theoretical analysis of the \(E_r C'_r\) process for the most favorable case of a very fast regeneration (where \(\tau\) is the pulse duration). A treatment for the more general case, involving stoichiometric factors other than unity in Equations (5) and (6), is also available.\(^{23}\)

The most successful version of the square-wave methods is SWV, which involves a fast variation of the polarization potential (typically, 10 V s\(^{-1}\)), thus combining a high sensitivity with a very short duration of the run. The theoretical treatment for the \(E_r C'_r\) mechanism shows that in the purely kinetic region (\(k_i c_0^A p > 2; p\) is the square-wave period) the response (known as the net current) increases in the peak current by a factor of \((\pi\tau k_i c_0^A)^{1/2}\) and \(c_0^A\).\(^{24}\) The modulation frequency has no effect on the current, but the lowest possible (e.g. 10 Hz) is recommended because this leads to a very low capacity current. An outstanding detection limit (2.5 \& 10\(^{-9}\) M) for Ti\(^{IV}\) determination by catalytic SWV in the presence of ClO\(_3^−\) as a substrate was reported.\(^{25}\)

AC polargraphy has not enjoyed so much attention as the other methods, although the theoretical treatment performed for the \(E_r C'_r\) mechanism, assuming planar diffusion at a constant-area electrode, demonstrates the same kind of favorable effect of the parallel reaction (as pointed out before). In the most favorable case of a very high reaction rate (\(k_i c_0^A \gg w; w\) is the angular frequency of the modulating sine wave) an increase in the peak current by a factor of \((k_i c_0^A /w)^{1/2}\) is predicted, compared with the diffusion current of \(P\) (i.e. the peak current recorded for \(k_i c_0^A = 0\)).\(^{11,26}\)

Under the above assumption, the peak current is not dependent on \(w\), because of the fast regeneration of \(P\), but it is directly proportional to \((k_i c_0^A D_P)^{1/2}\) and \(c_0^A\). A comprehensive review of the theory for AC methods including catalytic electrode reactions provides more details.\(^{9}\)

2.1.2.4 Hydrodynamic Voltammetry

The methods included in this class involve electrolysis under controlled and reproducible electrolyte flow conditions. Consequently, the mass-transfer process to the electrode fulfills the conditions for the steady state. Among the systems in this class, the most common are rotating disc, wall-jet, and the flow-through (tubular or channel) electrodes.\(^{27}\)

The latter types are applicable to continuous analytical measurement.

A general solution for the rotating disc electrode (RDE) is available in the case of the \(E_r C'_r\) mechanism (Equation 20):\(^{11,27}\)

\[
\frac{i_C}{i_d} = x \coth(x)
\]  

where \(x = 1.61 (v/D_p)^{1/6} (k_i c_0^A /w)^{1/2}\), \(v\) is the cinematic viscosity, and \(w\) is the angular velocity of the rotating disc. For a very fast regeneration the current amplification is \(i_C/i_d = x\).\(^{11,27}\) Under the same conditions, \(i_C\) is proportional to \(c_0^A\) (via \(i_d\)) and is not dependent on \(w\).

The theory for the \(E_r\) mechanism at a channel electrode\(^{28}\) gives the \((i_C/i_d)\) ratio as a function of a dimensionless kinetic parameter including the rate constant \(k_1\) and the electrolyte flow rate. The solution is available both as a series and as working curves. A number of variations in the \(E_r\) mechanism occurring at a channel electrode were recently examined by numerical computation.\(^{29}\) For the most simple case of an \(E_r C'_r\) mechanism, the current–voltage curves have the typical shape for a steady-state process, in agreement with Equation (14) with \(a = 1\). Although the solutions are more complicated than for the RDE, it is still clear that the amplification factor increases with an increase in both \(k_1\) and \(c_0^A\).

2.1.2.5 Adsorption Effects

Adsorption at the electrode interface is a common feature in electrochemistry of organic compounds or complexes containing organic ligands. It brings about a series of theoretical complications that originate in the deviation from the equilibrium state of the adsorption process or in the effect of electrode potential on the parameters of the adsorption isotherm. However, the adsorption of one or more participants in the catalytic process may favorably enhance the overall reaction rate as a consequence of the augmented local concentrations. Special advantages were demonstrated in the case of adsorptive stripping voltammetry (ASV) where the adsorption represents the basis for the preconcentration step.

A theoretical treatment for heterogeneous redox catalysis was performed under the assumption that the mediator couple is confined to the electrode surface as a monomolecular layer, either by irreversible adsorption or by another method of electrode modification.

When dealing with the CV of a nernstian system (\(E_r C'_r\)) the dimensionless kinetic parameter was defined as in
Equation (21)⁴³⁰

\[ \Lambda_s = k_3 \Gamma_T \left( \frac{RT}{FeD_A} \right)^{1/2} \] (21)

where \( \Gamma_T \) is overall surface coverage (\( \Gamma_T = \Gamma_P + \Gamma_Q \)). The overall current is the algebraic sum of the current produced by Equation (5) alone (\( i_c \)) and the purely kinetic component brought about by the occurrence of Equation (6) in the adsorbed state, \( i_s \). The effects of Equation (6) on the peak current and potential are available in a graphical form, as a function of both \( \Lambda_s \) and the departure from \( E^0_{P/Q} \).⁴³⁰ With the increase in \( \Lambda_s \), the \( i_c \) versus \( E \) curve changes in shape, from a sigmoid hysteresis-free curve to an asymmetrical peak. Simultaneously, the overall process turns from a kinetically controlled one (for small \( \Lambda_s \) values) to control by the diffusion of \( A \) when \( \Lambda_s \rightarrow \infty \). This change is accompanied by a strong increase in \( i_c \) and the shift of half-peak potential towards more negative values. The limiting value of \( i_c \) still cannot overcome the diffusion-controlled current of \( A \) at a bare electrode. Such conditions are suitable for the determination of the substrate.

If Equation (5), occurring in the adsorbed state, is followed by the formation of an adsorbed \( Q-A \) complex, an intramolecular electron transfer proceeds as Equation (6) and the product decomposes, leading subsequently to the regeneration of \( P \).⁴³¹ Assuming that the complex formation is at equilibrium and that Equation (5) is reversible, the relevant kinetic parameter \( \Theta \) was defined as in Equation (22):

\[ \Theta = k_3 K_{QA} \Gamma_T \left( \frac{RT}{FeD_A} \right)^{1/2} \] (22)

where \( k_3 \) is the rate constant for the intramolecular electron transfer, \( K_{QA} \) is the equilibrium constant for complex formation and \( \Gamma_T = \Gamma_P + \Gamma_Q + \Gamma_{QA} \). At a small, fixed value of \( K_{QA}d_A^0 (K_{QA}d_A^0 \leq 0.1) \), an increase in \( \Theta \) from 0.1 to 30 makes the peak current \( i_c \) increase towards a limit which corresponds to kinetic control by the diffusion of \( A \). Simultaneously, the shape of the \( i_c-E \) curve changes from sigmoid (which is characteristic of the absence of a noticeable concentration gradient of \( A \)) to the usual, peak-shaped form of the voltammogram. At the same time, the peak potential, which is dictated by the \( P:Q \) concentration ratio in the adsorbed state, shifts towards more positive values. At a constant and small value of \( \Theta \) (kinetic control), the increase in \( K_{QA}d_A^0 \) induces a decline in \( i_c \) with no marked change in the peak potential. The effect of \( K_{QA}d_A^0 \) is much less marked for \( \Theta > 10 \).

The above results also provide an interpretation of electrocatalysis at modified electrodes. With the bare electrode, at least some qualitative insight into heterogeneous catalysis can be drawn. For example, the above conclusion can be used for interpretation of the processes occurring in the quantitative determination of the catalyst by stripping voltammetry with adsorptive preconcentration. Under such circumstances, the presence of the catalyst in the bulk solution (usually, under \( 10^{-7} \) M) can be neglected and the catalytic effect is due to the adsorbed species only. In this case, one major deviation from the above treatments may be the reversible character of catalysis adsorption, leading to gradual desorption during the potential scan.

### 2.1.2.6 Electrocatalysis at Ultramicroelectrodes

The use of the UME (ultramicroelectrode), defined as an electrode with the characteristic dimension of 1 \( \mu \)m or less,⁴³² shows a series of advantages: small interference arising from capacity current and electrolyte resistance, allowing the use of highly resistive media including nonpolar solvents; the possibility of approaching steady-state mass transfer without convection; and suitability to microscale and in vivo analysis. Various UME shapes are disc, ring, disc array, hemisphere, band, cylinder and interdigitated array.

A particular feature of the UME is that the steady-state mass transfer occurs even in the absence of the convection, provided that the characteristic dimension (e.g. sphere radius \( r_s \)) is much lower than the thickness of the diffusion layer \((r_s \ll (D\tau)^{1/2}, \) where \( \tau \) is the timescale of the experiment, such as the pulse duration in DPP or duration of potential scan in LSV).⁴³³ Accordingly, a more general definition of the UME is proposed by Amatore⁴³⁴ who assumes that any electrode/electrolyte system shows the behavior of the UME if \( r_s \ll \delta \), where \( \delta \) is the thickness of the convection-free solution layer at the electrode surface. The factor \( \delta \) depends not only on \( D \) and \( \tau \) but also on the hydrodynamic conditions and electrolyte viscosity. Under such conditions, radial (convergent) diffusion prevails over planar diffusion. Rather than the dimension itself, the occurrence of radial diffusion is the main characteristic of a UME. In principle, this definition does not impose an upper limitation in the electrode dimension. However, it must be stressed that the advantages emerging from the small-capacity current and very small ohmic voltage drop arise only if the electrode dimension is under 100 \( \mu \)m.

The use of the UME for kinetic investigations has been reviewed by Montenegro.⁴³³ Under steady-state conditions, the diffusion-controlled reduction of the \( P \) species (Equation 5 alone) gives a sigmoid \( i_c-E \) curve (in accord with Equation 14) with a plateau corresponding to the limiting diffusion current \( i_d \). The occurrence of the \( E_{C_d} \) mechanism (with pseudo-first-order regeneration) induces a higher plateau current (\( i_c \)), according to...
Equation (23)\(^{(35)}\):

\[
\frac{i_c}{i_d} = 1 + \Lambda_m^{1/2}
\]  

(23)

with \(i_d\) as in Equation (24):

\[
i_d = \frac{FADc_0^0}{r_s}
\]  

(24)

The dimensionless kinetic parameter \(\Lambda_m\) is defined in Equation (25):

\[
\Lambda_m = \frac{r_s^2 c_0^0 k_1}{D}
\]  

(25)

Here, \(r_s\) is the radius for a hemispherical electrode (e.g., a mercury hemisphere electrolytically deposited on a Pt microdisc). The rate constant \(k_1\) can be determined from the slopes of the \(i_c/i_d\) ratio versus \(r_s\) plot (at constant \(c_A^0\)) or \(i_c/i_d\) ratio versus \((c_A^0)^{1/2}\) plot (at constant \(r_s\)). Alternatively, the above equations are easily rearranged aiming at data analysis by means of the \(i_c\) versus \(1/r_s\) plot.\(^{(36)}\) The pseudo-first-order conditions are fulfilled if \(c_A^0 \gg k_1 r_s^2 c_p^0 / D\).\(^{(37)}\) However, the occurrence of the steady state is favored by a high \(\Lambda_m/q\) ratio, where \(q\) is the dimensionless potential sweep rate (\(q = (Fv r_s^2 / RTD)^{1/2}\)).\(^{(35)}\) Empirically, the occurrence of the steady state can be demonstrated by the independence of \(i_c\) on \(v\) or by performing a logarithmic plot of the curve according to Equation (14). A more general treatment for the catalytic mechanism at a hemispherical electrode with application to chronamperometry, cyclic staircase voltammetry, and cyclic LSV was published recently.\(^{(38)}\)

In the case of a second-order regeneration, the solution of the relevant differential equations for a spherical electrode leads to Equation (26) (under the assumption of equal diffusion coefficients for all the species involved):\(^{(39)}\)

\[
\frac{i_c}{i_d} = 1 - \left( \frac{k_1 r_s^2 c_p^0}{2D} \right) + 0.5 \left( \frac{k_1 r_s^2 c_p^0}{D} \right)^2 + \left( 4\Lambda_m \right)^{1/2}
\]  

In contrast to the pseudo-first-order reaction, the relationship between the \(i_c/i_d\) ratio and \(r_s\) is nonlinear in this case. Interestingly, the pseudo-first-order kinetic regime appears as a limiting case of the second-order one if \(c_A^0 \gg k_1 r_s^2 c_p^0 / D\). In other words, for small values of \(k_1 r_s^2\) the process may assume pseudo-first-order character even if \(c_A^0\) is close to \(c_p^0\). Under these conditions, \(A\) is not depleted in the reaction layer and the \(A/P\) concentration ratio is very high here. Consequently, Equation (26) assumes the simple form of Equation (23).

The disc electrode (with radius \(r_d\)) was approached initially by asserting that it behaves like a hemisphere with an equivalent area and it is, therefore, sufficient to substitute \(r_s\) by \(\pi r_d^2/4\) in the relevant equations for the hemispherical electrode. It was shown later that this is a very rough approximation in the case of the catalytic process and rigorous equations were derived accordingly.\(^{(40)}\)

The effect of the difference between the diffusion coefficients was investigated by using the reaction layer concept.\(^{(41)}\) Kinetic equations were derived under such conditions for either the first- or second-order homogeneous catalytic reaction at an ultramicrodisc electrode. In accord with the results for the spherical UME presented above, the reaction order can be controlled by changing the dimension of the UME. Thus, the second-order reaction can be changed to quasi-first-order by decreasing the dimension of the UME.\(^{(42)}\)

It was stated that the microcylinder electrode shows important advantages from the standpoint of both theory and experiment. The theory of the \(EC_n^c\) mechanism with a second-order parallel reaction was worked out using the concept of the reaction layer and was applied to the \(Fe^{III} - ethylenediamine tetraacetic acid (EDTA) – H_2O_2\) system.\(^{(43)}\)

Although the steady state seems to be typical of the UME, the nonsteady state may also be attained. This occurs for a very low timescale \((r_d \gg (Dt)^{1/2})\) and involves the planar diffusion. Under such conditions, the experimental data can be dealt with in the classical way (sections 2.1.2.2 and 2.1.2.3), with the advantage of a very low \(\tau\) value, which allows the investigation of very fast electrode reactions.

2.1.2.7 Intramolecular Electron Transfer as a Regeneration Step As shown before, most of the available theoretical treatments of catalytic electrode reactions assume that the parallel chemical reaction proceeds via an outer sphere mechanism. Nevertheless, the occurrence of the opposite mechanism, involving a catalyst–substrate adduct, cannot be ruled out as was mentioned in section 2.1.2.5. The formation of a substrate–catalyst complex may occur, for example, in the case of some processes involving oxo cations as catalysts and hydrogen peroxide as the substrate.\(^{(44)}\) This kind of mechanism is easily detected in DC polarography by the direct proportionality relationship between the \(i_d/i_c\) ratio and 1/\(c_A^0\).\(^{(45)}\) The catalytic limiting current is directly proportional to substrate concentration under pseudo-first-order conditions and for \(c_A^0 \gg K_{OA}\). Such conditions are appropriate for the substrate determination with a sensitivity that is directly proportional to the concentration of the catalyst.

2.1.3 Some Examples of Parallel Electrochemical Systems Many early investigations were performed by DC polarography and a detailed compilation of the results
is available. Data included in this review could provide useful information for developing analytical methods based on more advanced electroanalytical techniques.

Commonly, inorganic oxidants are used as substrates, including either neutral (hydrogen peroxide, hydroxylamine) or anionic species (chlorite, chlorate, perchlorate, bromate, iodate, nitrate, nitrite, persulfate ions). The mediator may be, in principle, any transition metal which shows two stable oxidation states. Metals in groups Ib (Cu), IVb (TiIV), Vb (Vv), VIIb (CrIII, MoVI, WVI), VIII (FeIII, CoIII, RuIII, OsVIII) as well as some lanthanides (YIII) and actinides (UVI) can be mentioned in this connection and appropriate methods for the polarographic determination of such metal ions were quoted. An organic mediator (4-hydroxy-2,2,6,6-tetramethyl-piperidinoxy radical) which catalyzes the anodic oxidation of hydrazine on a carbon electrode was also reported.

Although Scheme 1 may accurately describe many real systems, frequent deviations occur due, for example, to the simultaneous occurrence of different chemical states of the catalyst, double-layer effects on reactions involving charged particles, and adsorption of complexes with organic ligands. A careful empirical optimization of the experimental parameters still allows the use of complicated processes for analytical purposes, even if the rigorous kinetic investigation is not possible.

Because the substrate is very often a covalent compound, Equation (6) may consist of several steps involving free-radical species. For example, in the FeIII/FeII -H2O2 system this reaction occurs as shown in Equations (27) and (28):\(^{6,8}\)

$$\text{Fe}^{2+} + \text{H}_2\text{O}_2 \rightarrow \text{Fe}^{3+} + \text{OH}^- + \text{OH}^* \quad (27)$$

$$\text{Fe}^{2+} + \text{OH}^* \rightarrow \text{Fe}^{3+} + \text{OH}^- \quad (28)$$

Analogously, hydroxylamine reduction by either Fe2+ or TiIII involves NH2• or OH• radicals.\(^{6,8}\)

In the presence of a radical scavenger, such as ethanol or an organic ligand in excess, the stoichiometry of the regeneration step will change. Accordingly, the stoichiometric factor of Equation (5) should be included in the kinetic equation as a multiplier for \(k_1\). This factor indicates how many times Equation (5) occurs for each occurrence of Equation (6), i.e. it is the ratio of the stoichiometric coefficients of \(Q\) in Equations (6) and (5). Thus, for the Fe2+ –H2O2 system (Equations 9 and 10), the stoichiometric factor is two but it decreases towards one in the presence of ethanol. Consequently, the presence of radical scavengers will produce a drop in sensitivity. Detailed investigations on this topic have been made with special reference to LSV.\(^{19}\)

Hydrogen peroxide is by far the most widely applicable substrate and many of the above-mentioned mediators react with it giving catalytic currents for potential analytical applications. Some particular features are the effect of pH on H2O2 oxidizing power and the formation of peroxy complexes of various catalyst ions (Ti, V, Mo, W, Nb, Hf, Zr, Ta) followed by a shift in the redox potential of the metal ion to less negative values.

Hydroxylamine also shows a broad area of applications (for Nb, Ru, and W). Chlorate and bromate ions are also strong oxidants with many possible applications, but the negative charge may lead to intricate polarographic shapes, especially when the mediator itself is an anion, such as MoVI or WVI. Worthy of mention is the catalytic current of selenium (after reduction from SeO3^2- to H2Se and redox cycling between this state and Se0) in the presence of BrO3-. Perchlorate ion is a milder oxidant and only MoVI and WVI give catalytic currents in its presence. The catalytic activity of MoVI and WVI is depressed by complex formation. Iodate and periodate provide catalytic currents for organic sulfur compounds, such as for the cystine/cysteine couple.

2.1.4 Analytical Applications

Redox-type electrocatalytic processes can be used to determine the catalyst, the substrate, an activator or an inhibitor of the redox reaction; the first of these applications is most usual. Substrate determination may be more conveniently done by electrocatalysis at a modified electrode (section 3), although the advantages of bare electrodes (readily available, reproducible response and a broad field of application) can very often decide in favor of the latter kind of electrode.

2.1.4.1 Selection of Experimental Conditions

The experimental conditions for either catalyst or substrate determination can be decided using the kinetic zone diagram.\(^{47}\) This shows the occurrence of various kinetic regimes as a function of two dimensionless parameters that include both intrinsic (rate constants) and operational factors (the timescale and reactant concentrations). The simplest procedure for dealing with the kinetic data corresponds to limiting kinetic regimes and such conditions are also optimal for analytical determination. Figure 2 shows the kinetic zone diagram for the EE-Cu mechanism under the conditions of LSV. The relevant parameters are \(\gamma = c_A^0/c_B^0\) (the excess factor) and \(\lambda_1 = (k_1c_B^0/v)(RT/F)\). The arrows on the right-hand side of the figure represent the direction and the magnitude (in log units) of the shift produced by intrinsic \((k_1)\) and operational \((v, c_A^0, c_B^0)\) factors.

In the purely kinetic zone K, fast substrate consumption leads to a purely kinetic regime involving mutual compensation between the parallel chemical reaction and the diffusion process. A limiting case of this situation that corresponds to a very low \(\lambda_1/\gamma\) ratio is represented by
the KS zone. Here the substrate concentration is constant throughout the solution and the diffusion effect is negligible. Consequently, the voltammogram shows the characteristics of the steady state, that is, it is S-shaped, with the half-wave potential equal to \( E_{P/Q}^0 \) and the plateau current is in accord with Equation (17), i.e. directly proportional to \( c_P^0 \). Such conditions are suitable for catalytic determination with the sensitivity proportional to \( (c_P^0)^{1/2} \).

In the opposite case of total catalysis (KT), the substrate consumption is so fast that the rate-determining step is the diffusion of the substrate. This makes this kinetic zone suitable for substrate determination. Under these conditions, the catalytic process produces a peak located well ahead of the standard potential of the P/Q couple.

The KD zone represents the transition from pure diffusion control (no catalysis) to pure kinetic control. In the KG and KG* zones, some complications arise from the tendency of the voltammogram to split into two waves, the potential separation and relative heights of which are functions of both \( \lambda_1 \) and \( \gamma \).

As is usual in kinetic analysis, the signal is strongly dependent on the chemistry of the system. The mediator-binding ligands (activators) may strongly influence the rate of the regeneration reaction and its proper selection will improve the sensitivity dramatically. The pH is also an important factor, as it may influence various processes such as metal ion hydrolysis, complex formation and substrate protonation. The presence of radical scavengers, with negative effects on sensitivity, has to be avoided. Temperature should be carefully controlled in view of its strong effect on the catalytic current via the rate constant \( k_1 \). However, this could be an advantage as the sensitivity strongly increases with temperature.

It is also worth mentioning the potential applications of electrocatalysis in microheterogeneous fluids. Surfactant aggregates (micelles, microemulsion) can enhance the rate of the parallel reaction by bringing the reactants together in local higher concentrations. This results in enhanced sensitivity and makes nonpolar substances amenable to electroanalysis in an aqueous milieu.

2.1.4.2 Catalyst Determination

This is by far the most important analytical application of redox catalysis at bare electrodes, enabling an appreciable enhancement in sensitivity. Substrate selection is important for achieving convenient analytical figures of merit. First, the substrate must be selected taking into account its redox potential with respect to that of the mediator (section 2.1.1). Additionally, a high rate constant for the parallel reaction, as well as some affinity of the substrate towards the mediator, may improve the sensitivity. Although dated, the survey by Mark and Rechnitz of the redox reactions from the kinetic viewpoint provides a good theoretical starting point for rationalizing the analytical applications of redox catalytic electrode processes. More recent monographs afford a deeper insight of the molecular basis of redox reaction.

Most of the early applications of redox catalysis at bare electrodes have been reviewed and refer to industrial, geological and biological samples. The most impressive progress in this field results from the combination of ASV with redox catalytic processes. In ASV the preconcentration is made by the adsorption of the analyte (here, a metal ion in complex form) on the electrode surface at an appropriate potential. During the subsequent potential scan, the adsorbed species undergoes an electrode reaction that produces the analytical signal as a current peak. This method is very convenient for the determination of most of the transition metals that cannot be concentrated as an amalgam in the mercury drop electrode. If the electrode reaction is accompanied by a redox reaction, which regenerates the initial form, the sensitivity is greatly enhanced. Also, the selectivity can be ameliorated in this way. The selection of the ligand is crucial – it must possess a high surface activity so as to enable the adsorptive preconcentration and it must not alter the redox properties of the analyte. It is particularly advantageous that the ligand (which is usually added in excess) also does act as a substrate. In this case, the parallel reaction involves two adsorbed partners and the reaction rate may increase accordingly.

Some selected examples of analytical applications of redox catalysis at bare electrodes are included in Table 1.

2.1.4.3 Substrate or Ligand Determination

The catalytic determination of the substrate may be advantageous from several standpoints. First, it makes possible

b The ligand also acts as a substrate/oxidant.

determined of some compounds that show electrochemical properties not suitable for electroanalytical quantitation. Second, the electrochemical process proper involves the mediator and, by an appropriate mediator selection, the electrochemical response may be shifted beneficially along the potential axis. No special advantages from the standpoint of sensitivity can be expected under the conditions of the steady-state methods (namely DC polarography and RDE voltammetry) because the response cannot overcome the diffusion current of the substrate. However, the sensitivity and detection limit can be substantially improved when using nonsteady-state methods (e.g. DPP, SWV or AC polarography) provided that the mediator undergoes a reversible electrode reaction. This advantage results from the dependence of the response on the rate constant for the electrode reaction, $k_s$. An important detail related to the form of the calibration graph is the occurrence of a nonzero signal even in the absence of the analyte substrate. This is due to the simple electrode reaction of the mediator.

Although not so frequent as the applications for catalyst determination, the catalytic substrate determination may prove very useful as, for example, in the determination of trace nitrate (with U$^{VI}$ as catalyst),$^{62}$ H$_2$O$_2$ (on a copper electrode, with anodically generated Cu$^+$ as catalyst),$^{63}$ hydrazine,$^{46}$ or hydroxylamine$^{64}$...
(with 4-hydroxy-2,2,6,6-tetramethyl-piperidin-1-oxyl as catalyst).

Catalytic redox processes may also be used for the determination of a ligand, provided that the complex compound differs from the noncomplexed mediator in both the standard potential and catalytic activity. The distinct wave of the complex is amplified by an appropriate substrate in order to improve the sensitivity. In this respect, the determination of some hydroxyacids and polyphenols using either the TiIV–ClO3− or MoVI–ClO3− systems has been investigated. Analogously, phosphate ion may be determined as molybdophosphoric acid in the presence of ClO3−. Nitrite ion may be determined after disproportionation to nitrogen oxide which is thereafter included in the [Fe(SCN)(NO)]+ complex. This gives a catalytic current in the presence of dissolved oxygen.

2.2 Indirect Electrocatalytic Methods

This class of methods includes electrode processes with no electron transfer to or from the catalyst species. Interaction with the substrate occurs so as to decrease the activation energy of the electrode reaction and thus generates a new electrochemical signal with a distinct position on the potential axis.

2.2.1 Ligand-catalyzed Metal Ion Reduction

The catalytic reduction of some metal ions was first detected for Ni2+ or Co2+ by DC polarography in the presence of some aromatic diamines, pyridine or its derivatives, and aminothiols such as cysteine and its derivatives.

The catalytic process induces a prewave whose half-wave potential may be hundreds of millivolts positive with respect to that of the main (irreversible) wave due to the hydrated metal ion, Mn+ (Figure 3). It is obvious that a complex compound is reduced in the potential range of the prewave. The catalytic character of this process is demonstrated by the high $i_k/i_d$ ratio, where $i_k$ is the limiting current of the prewave and $i_d$ denotes the expected diffusion current of the reducible complex compound. That is, the catalytic prewave occurs at a very low ligand/metal ratio, usually less than 0.1. The solution pH is an important parameter that decides the occurrence of the prewave via the formation of the reducible complex. Very often, the prewave is bell shaped (Figure 3).

An elementary description of the catalytic reduction of the metal ion is given by Equations (29) and (30) where L is the ligand catalyst (Scheme 2). The charges for L and the complex species are omitted for simplicity.

Provided that the metal ion is present in high excess and is not significantly depleted, the rate-determining step is the regeneration of the reducible complex. This characteristic is demonstrated by the absence of any mass transfer effect on the prewave current. Experimentally, the absence of any effect of the mercury column pressure (in DC polarography) or potential scan speed (in LSV on a stationary electrode) is an indication of kinetic control by the chemical regeneration step.

This simple reaction scheme is often complicated by additional factors: ligand protonation; occurrence of a series of successive complexes; ligand adsorption (often under nonequilibrium conditions); the effect of electrode potential on the adsorption degree; and double-layer effects on the concentrations of charged reactants in the reaction layer. Attempts to set up a theoretical approach taking into account the above factors yielded only a partial description of the process. However, a search for...
systems showing simpler behavior enabled the catalytic current theory presented in section 2.1.2 to be used, by substituting [ML] for P, L for Q, and M$^{n+}$ for A. This procedure is suitable in the absence of adsorption and if the formation of higher complexes is prevented. In this way, either DC polarography or LSV has been used for the determination of rate and equilibrium constants for the parallel, complex-forming reaction in the case of nickel reduction catalyzed by nicotinamide$^{[72,73]}$ or 6-mercaptopurine riboside.$^{[74]}

When the ligand adsorption has to be accounted for, two main problems arise. First, when using the dropping mercury electrode, the surface concentration is not accurately given by an adsorption isotherm because the equilibrium state cannot be achieved during the short lifetime of each drop. Conversely, if a hanging mercury electrode is used instead, the adsorption equilibrium could be attained by a prolonged contact with the solution at a given potential. However, during the potential scan, the equilibrium is disturbed by the shift in the value of the adsorption coefficient.$^{[75]}$ A favorable situation arises when the diffusion-controlled adsorption of the catalyst is the rate-determining step because, under such conditions, the kinetic equation relating the current to catalyst and reactant concentration can be derived.$^{[71]}

As far as the stoichiometry of the reducible complex is concerned, a direct correlation of the equilibrium data with the prewave current in the Ni$^{2+}$–penicillamine system demonstrated that the metal/ligand ratio is 1 : 1.$^{[76]}$ This value is similar to that determined in an indirect way for other ligands.$^{[71,72,74]}$ and seems to be typical for the catalytic reduction of the metal ion.

The catalytic prewave of the metal ion enables sensitive determination of the ligand catalyst, which may be electrochemically inactive and not amenable to electrochemical determination by other methods. The sensitive determination of pyridine.$^{[67]}$ methionine.$^{[77]}$ or the alkaloid pilocarpine.$^{[78]}$ in the presence of Ni$^{2+}$ can be mentioned as examples. Noteworthy progress in this field has emerged by using catalytic reduction of the metal ion as a detection process in stripping voltammetry.$^{[79–82]}$ Detection limits down to 10$^{-9}$ M can be achieved in this way for compounds showing catalytic properties in the reduction of Ni$^{2+}$ or Co$^{2+}$.

Moreover, the dependence of catalytic activity on subtle features of the catalyst structure enables selective determination of the catalyst in the presence of related compounds. For example, o-phenylenediamine can thus be determined in the presence of its meta or para isomers by DC polarography.$^{[67]}$ Analogously, cysteinyI dipeptides have been determined in the presence of their constituent amino acids.$^{[71]}$ Cathodic stripping voltammetry allows the simultaneous determination of either cysteine or penicillamine (as a catalyst) and N-acetyl cysteine (a noncatalytic compound) in the presence of Ni$^{2+}$.$^{[79,80]}$

### 2.2.2 Hydrogen Evolution on Mercury Electrodes Catalyzed by Organic Bases

Hydrogen evolution on the mercury electrode occurs with an extremely high overvoltage. Some organic compounds (proteins, various alkaloids, pyridines and their derivatives, other heterocyclic nitrogen compounds) may reduce the hydrogen overvoltage giving a typical polarographic wave (Figure 4). Its current is much higher than any expected diffusion current in the system. This wave was ascribed a catalytic character$^{[83]}$ and is sometimes called a presodium wave, in view of the experimental circumstances that led to its discovery. The organic catalyst must be able to bind a proton, which subsequently enters the electrode reaction. That is why the catalytic wave obviously occurs in buffer solutions at a pH close to the pK$_a$ of the catalyst.

Several interpretations of the catalytic hydrogen evolution by organic nitrogen bases have been proposed.$^{[83]}$ The most elaborate$^{[84]}$ postulates that the electron uptake by the protonated catalyst (BH$^+$) produces a radical, BH$. Thereafter, the radical dimerizes leading to regeneration of the catalyst in the nonprotonated form (2BH$^+$ $\rightarrow$ 2B + H$_2$). The B$^*$ form is subsequently protonated via reaction with the acid component of the buffer. The bell-shaped form of the catalytic wave was explained by two opposite effects of the potential shift towards more negative values – an increase in the rate constant for the electron transfer reaction (according to the Butler–Volmer equation), and a drop in the surface concentration of the catalyst.

![Figure 4](image-url)
This interpretation was recently criticized from two standpoints. First, it is stressed that the catalyst is a reduction product of the nitrogen base present in the solution and not the base itself. Second, a key step in the mechanism, i.e. dihydrogen production by radical dimerization, has never been proved directly by the methods of organic chemistry.

Despite the uncertain mechanism, this electrode process has proved useful in the very sensitive determination of various compounds of pharmaceutical relevance.

2.2.3 Platinum Metals Catalysis of Hydrogen Evolution on Mercury Electrodes

The wave recorded in acidic solutions containing platinum metal ions was ascribed to hydrogen evolution on metal microcrystals that form on the mercury electrode surface by metal ion reduction. The wave height increases in the sequence Ru$^{III} >$ Rh$^{III} >$ Ir$^{IV} >$ Pt$^{IV} >$ Pd$^{IV}$ and enables extremely sensitive determinations (e.g. $5 \times 10^{-10}$ M ruthenium).

More recently it has been shown that some platinum complexes with organic ligands (such as ethylenediamine or formazone) behave analogously. Moreover, the organic ligand enables adsorptive accumulation of the metal ion in view of the stripping voltammetric determination with detection by means of the catalytic hydrogen current. It is thus possible to detect Pt at the ultratrace level in biological, environmental and geological samples. The ligand itself, or a compound that generates the ligand by an appropriate chemical reaction, can also be determined in this way. Analogous applications for other platinum group metals have been reported.

2.2.4 Hydrogen Evolution on Mercury Electrodes Catalyzed by Transition Metal Complexes

The most typical behavior of this feature is shown by sulfur-containing amino acids or proteins in the presence of cobalt ions in the ammonia buffer at pH about 9.5. The catalytic wave occurs in the potential range of the diffusion current for Co$^{2+}$ reduction and has the shape of a round maximum in the case of the small molecular mass compounds (Figure 5). Under the same conditions, proteins give a particular double wave (Figure 6). This kind of polarographic wave is often termed a Brdička wave after the name of the discoverer. Under the same conditions, Ni$^{2+}$ gives lower catalytic currents. Analogous electrode processes may occur in the presence of other ligands containing sulfur, selenium, nitrogen or phosphorus.

It is clear that the catalytic wave is due to a metal complex, which must be present at the electrode surface. A common feature is that the ligand is strongly polarizable and may accept electron pairs from the metal ion in an empty π or d orbital. In this way, unusual low-valence states of the metal ion (+1 or 0) may be stabilized. The catalytic complex is usually a chelate species, although this is not a general rule.
Two different assumptions have been made about the nature of the catalytic complex. The first assumes that this complex contains the metal ion in the normal oxidation state (2+), but its reduction potential is shifted to more negative values as an effect of complexation.\(^{97}\) This complex is reduced in the potential range of the catalytic wave, simultaneously with catalytic hydrogen evolution. Consequently, the gradual decrease in the interface concentration of the catalytic complex produces a drop in the wave current after reaching a maximum (Figure 5).

The alternative interpretation assumes the catalyst to be a zero-charged metal complex, which results from the electroreduction of the normal complex present in the solution.\(^{98}\) In this instance, the round shape of the catalytic hydrogen wave may be ascribed to the effect of the electrode potential on the surface concentration of the adsorbed organic ligand.\(^ {84}\) It is possible that either of the above mechanisms may be operative, depending on the properties of the ligand. As a common detail, both interpretations point out that the maximum current is not a true limiting current.

The occurrence of a double wave in the case of the proteins may be due to either the occurrence of two catalytic complexes with different properties\(^ {97}\) or to some changes in the adsorption layer due to the shift in the potential value.\(^ {84}\) Despite the complexity of the reaction mechanism, the effect of some experimental parameters on the protein double wave is fairly accounted for by the equations derived under the assumption of the diffusion-controlled catalyst adsorption.\(^ {99}\)

A more advanced decrease in hydrogen overvoltage on the mercury electrode occurs in the presence of Ni\(^ {2+}\) and cysteine or related compounds, at pH 6–7.\(^ {100,101}\) The catalytic hydrogen prewave thus produced \((E_{1/2})\) about \(-1.2\) V versus SCE: Figure 3) shows many distinct characteristics when compared with the Brdicka wave and is much more sensitive to small changes in ligand structure. In this instance, the occurrence of hydride ion as an intermediate that coordinates the metal center is highly probable, in accord with recent representations of hydrogen evolution catalyzed by metal complexes.\(^ {102}\) The relevant electrode process was suggested as a model for hydrogenase-catalyzed hydrogen bioproduction.\(^ {101,103}\)

Catalytic hydrogen evolution enables very sensitive determination of the organic ligand, and various applications in biochemistry and medicine have been reported.\(^ {98}\) Much effort has been devoted to establishing a cancer test based on the Brdicka wave.\(^ {95,96}\) Although such a method appears now to be of purely historic interest, the Brdicka reaction still proves useful in some applications.\(^ {104–106}\) After being optimized for DPP, it now enables the determination of minute amounts of proteins \((0.1–1\) mg L\(^{-1}\)).\(^ {107}\) In this version, it is one of the standard methods for the determination of metallothionein.\(^ {108,109}\) The Brdicka wave also enables the simultaneous determination of hemoglobin and cysteine.\(^ {110}\) Other sulfur-containing organic compounds may be similarly determined.\(^ {111,112}\)

The catalytic hydrogen evolution in the Co\(^ {2+}\)–SH\(^{-}\) system has been employed as a detection process in cathodic stripping voltammetry of sulfide ion on the mercury electrode.\(^ {113}\) Some organic sulfur-containing compounds can be determined in the same way after the carbon–sulfur bond splits during the deposition step at a sufficiently positive potential.\(^ {114}\)

The catalytic wave is also useful for the determination of the metal ion itself, as a component of the catalytic complex. This method brings about a spectacular enhancement in sensitivity. Accordingly, the most important electroanalytical methods for nickel and cobalt determination are based on the catalytic hydrogen evolution in the presence of dimethylglyoxime.\(^ {115}\) The catalytic ligand may also enable adsorptive preconcentration of the metal ion on the hanging mercury drop electrode, in view of the stripping voltammetric determination, with detection by the catalytic evolution of hydrogen.\(^ {115,116}\)

Some metal complexes of practical importance (e.g., fungicides) can be determined by the catalytic wave induced by the constituent sulfur-containing ligand.\(^ {117}\) Some metal ions can also be determined indirectly, after performing the extraction as a chelate with a ligand that is able to produce the catalytic hydrogen wave (dithiocarbamates, xantogenates, 8-mercaptopquinoline).\(^ {117}\)

### 3 ELECTROCATALYSIS AT CHEMICALLY MODIFIED ELECTRODES

#### 3.1 General Aspects

The properties of the electrode can be deliberately modified by immobilizing a reagent on its surface so that the modified electrode displays the properties of the immobilized compound. Reagent immobilization can be done by chemical (irreversible) adsorption, covalent bonding, or film deposition.\(^ {118,119}\) The composite electrodes, consisting of a mixture of conducting powder (e.g., carbon), a modifier and a hydrophobic binder, may also be included in this class. Depending on the modifier properties, the electrode may achieve various functions, such as preconcentration of the analyte, permselectivity, detection of some electroinactive species, or electrocatalysis.

As a research field, electrocatalysis at a CME is mostly directed towards mediated electron transfer via an immobilized redox couple. An immobilized redox couple may act as a shuttle for electron transfer between...
the electrode and some substrate, which would otherwise undergo a slow electrochemical reaction. This process is fairly described by Equations (5–7) with the important difference that the mediator is bound to the electrode surface and only the substrate and the products take part in mass transfer processes in the bulk of the solution (Figure 7). The catalyzed reaction often involves the transfer of several electrons, the breaking of some chemical bonds and the formation of new ones. In order to increase the reaction rate for such a complicated process, some intermediate must be stabilized by interaction with the modifier.

The thermodynamic requirement for electrocatalysis to occur is the same as for the homogeneous system (section 2.1.1). The catalyzed reaction proceeds at the formal potential of the mediator couple, provided that no catalyst–substrate adduct forms (Figure 8). The mediator must be able to undergo a very fast electron transfer reaction, i.e. the reorganization of the coordination sphere should involve a small Gibbs energy change. This condition is fulfilled by complexes of transition metals (e.g. ferrocene and cyano complexes of iron and ruthenium) and organic molecules with a large π-bond system (e.g. phenoxazine, tetrathiafulvalinium tetracyanoquinodimethane (TCNQ)). A comprehensive description of various mediators with modified carbon electrodes is available.\(^{120}\)

Metal powders dispersed in a conductive matrix are efficient catalysts for the electrooxidation of various organic compounds. Specific interaction with the substrate rather than mediated electron transfer may be the source of the catalytic activity in this instance.

### 3.2 The Modifier as a Thin Layer

Submonolayer or monolayer coverage is achieved by irreversible adsorption from solution or by placing a small, accurately measured volume of the modifier solution on the electrode surface and letting the solvent evaporate. This straightforward method suffers from a poor reproducibility, and leaching of the modifier slowly damages the resulting layer. It is still useful for a preliminary investigation of some modifiers.\(^{118,119}\)

### 3.3 Electrocatalysis at Redox Polymer Modified Electrodes

#### 3.3.1 Homogeneous Polymer Films

A redox polymer contains spatially localized redox sites. They can be bound covalently by being built into the chain or as a pendant group, such as osmium and ruthenium poly(pyridyl) polymers.\(^{121}\) An alternative is electrostatic binding to an ion-exchange polymeric system, such as Ru(bpy)\(_3\)\(^{3+}/2+\) included in a Nafion™ layer. In contrast to the monolayer, the polymer film forms a tridimensional structure containing up to \(5 \times 10^{-6}\) mol cm\(^{-2}\) redox groups, providing a far greater number of reactive sites.

Most polymer modification procedures can be classified as either deposition of preformed polymers or electrochemical polymerization. Charge transport inside the polymer layer occurs by an electron exchange process between neighboring sites (self-exchange reactions, electron hopping, and redox conduction are alternative terms for this process). Simultaneously, transport of the co-ion in the opposite direction occurs to preserve electroneutrality, which is why the nature and the concentration of the background electrolyte may play a very important role in the charge transport process.
Redox catalysis at a CME occurs via a substrate–mediator electron-transfer reaction that may proceed either at the outer surface of the polymer film (surface reaction), or inside the coating with the substrate undergoing diffusion within the modifier layer.\textsuperscript{122–124}

Two different theoretical models, leading to similar results, are commonly quoted. In the model of Albery and Hillman\textsuperscript{125} two reaction layers are assumed. The first, located close to the film/electrolyte interface, is the zone where the substrate reaction with the mediator occurs. The other (near the electrode/film interface) corresponds to the electron transfer to (or from) the mediator. In the approach of Savéant et al.\textsuperscript{126,127} no reaction layers are identified but the process is described in terms of four characteristic currents: substrate diffusion across the film; diffusion-like electron characteristic currents; substrate diffusion in the solution; and electron transfer (or back transfer) to (or from) the mediator.

3.3.2 Microheterogeneous Polymer Layers

As previously discussed, the modifier film performs two parallel functions simultaneously, namely charge transport to the catalytic site and the catalytic activity. Conversely, a distinct component fulfills each function in the case of a microheterogeneous polymer. This provides more flexibility when designing a CME for a selected purpose. The coating may contain metal or metal oxide microparticles dispersed inside an electronically conducting polymer (polypyrrole, polyaniline), an ionically conducting polymer (Nafion\textsuperscript{126}), or a redox polymer. The kinetic analysis of such a system must take into account two additional factors: substrate diffusion towards the catalyst particle within the matrix, and the charge transfer reaction at the particle surface.\textsuperscript{122–124}

3.4 Electrodes Modified by Inorganic Films

Electrodes modified with sparingly soluble inorganic films promise better stability than polymer film CMEs.\textsuperscript{130} For example, metallophthalocyanines and porphyrines, as components of composite modified electrodes, are efficient catalysts for the oxidation of hydrazine, hydroxylamine, nitrite\textsuperscript{133} and As\textsuperscript{III} (130) as well as reduction of O\textsubscript{2}, H\textsubscript{2}O\textsubscript{2} and Fe\textsuperscript{III} (130) are examples of electrochemical reactions catalyzed by such CMEs.

Other inorganic films with promising properties have been reviewed.\textsuperscript{130} Lower metal oxides (PtOH, AuOH), nonstoichiometric, mixed-valence metal oxides (tungsten and molybdenum bronzes), and doped metal oxides show catalytic properties towards the oxidation of various organic compounds.

3.5 Carbon Paste Electrodes and Other Composite Electrodes

Graphite powder (5–20\,\mu m particles) is mixed with an inert binder, such as paraffin or mineral oil, to form a paste that is typically 70% carbon by weight. The paste is packed into a shallow well in an inert holder with electrical contact at the back. A solid composite electrode may be prepared by using a filler like Kel-F\textsuperscript{134}, Teflon\textsuperscript{8}, epoxy resin or polyethylene.\textsuperscript{134} To prepare a CME, a modifier reagent is either dissolved in the binder or physically mixed with the paste.\textsuperscript{134,135} This is one of the most straightforward ways to prepare CMEs with highly reproducible properties.\textsuperscript{134,136} Screen-printed electrodes, prepared by adding the catalyst to carbon ink,\textsuperscript{137} can be also included in this class. A large diversity of inorganic (metal phthalocyanines, metalloporphyrins, hexacyanoferrates(III), metal powders, metal oxides and various complexes) or organic (phenoxazines, phenothiazines, quinone/hydroquinone) redox mediators are effective modifiers for carbon paste electrodes.

3.6 Electrocatalysis at Electronically Conducting Polymer Electrodes

In contrast to a redox polymer that contains distinct redox sites separated by nonconducting molecular fragments, an electronically conducting polymer (such as polypyrrole, polythiophene and their analogs) possesses extended \pi orbitals that facilitate continuous electron flow along the macromolecule. In some cases electrocatalytic activity is ascribed to the polymer itself, with no additional components. Thus the electrocatalytic mechanism may not be redox-mediated electron transfer, but the result of some favorable interaction between the substrate or some intermediates and the organic electrode surface. Some promising applications (for the detection of neurotransmitters, ascorbic acid, and other compounds of biological relevance) have been reviewed.\textsuperscript{138}
3.7 Guidelines for Analytical Applications of Electro catalytic Determinations at Chemically Modified Electrodes

From the analytical standpoint, electrocatalysis at CMEs can be used in two ways: the determination of the substrate by means of the catalyst-modified electrode; and for the determination of the catalyzed by an electrochemical stripping method, after its accumulation on a properly designed CME.\(^{139}\)

Substrate determination represents by far the most frequent application of CMEs for the analysis of various samples of environmental, biomedical and biotechnological relevance.\(^{120,130,132,134,136–138,140–142}\)

Optimum conditions for electrocatalytic determination of the substrate at a CME are met when the rate-determining step is the mass transfer of the analyte in solution while charge propagation within the film is very fast.\(^{142}\) A linear calibration graph results under such conditions and the kinetic complications are absent. Inorganic species appropriate for quantitation by such a method include oxygen, hydrogen peroxide, hydrazine, hydroxylamine, nitrogen and sulfur anions. Many more applications have been reported for organic and biochemical analyses (cysteine and derivatives, thiourea and derivatives, carbohydrates, polyalcohols, \(\alpha\)-keto acids).

Although CMEs have important advantages as sensors for batch analysis, the most promising applications are chemical sensors for field analysis, single-use sensors, and detectors for the analysis in flowing systems (flow injection analysis, liquid chromatography).\(^{143}\) For detection in liquid chromatography, the problem of selectivity is not critical. Conversely, a low selectivity may be an advantage as it allows the detection of different compounds after performing the chromatographic separation. A serious problem with such detectors is the mechanical abrasion, but a permeable protecting coating over the catalytic layer can prevent this inconvenience.

As a result of their small size, modified UMEs have special advantages for microchemical-scale analysis, in vivo analysis,\(^ {144}\) or as detectors in capillary electrophoresis.\(^ {145}\)

4 AMPEROMETRIC ENZYMATIC DETERMINATIONS

4.1 Background

The outstanding specificity of enzymes as catalysts makes them very attractive for analytical purposes. Hence, enzymatic analysis is a well-established branch of analytical chemistry. Electrochemical methods can be used to monitor the enzymatic reaction occurring in the solution phase, but such a procedure is obviously not convenient owing to the consumption of the enzyme and other expensive reagents. The main interest in this field is therefore directed towards the development of electrochemical enzymatic sensors. The sensor consists of a reagent layer (including the enzyme) in close contact with a transducer that generates the measurable signal. The reagent layer performs the sensing (recognition) function by enzyme-catalyzed conversion of the substrate. Either potentiometric or amperometric transduction methods have been proposed, both showing some particular advantages. Whereas potentiometric transduction involves passive electrochemical devices, the amperometric version frequently relies on the integration of the electrochemical transducer in the electron transfer chain with the substrate at one end and the electrode at the other. At least one step in this dynamic process is an enzyme-catalyzed reaction, which justifies the classification of such procedures as electrocatalysis-based methods. Owing to the electrochemical nature of the transduction process, the most suitable enzymes belong to the oxido-reductase class, with glucose oxidase (GOD; EC 1.1.3.4) being a characteristic example.\(^ {146}\)

A simplified view of the function of an amperometric enzymatic sensor is described by Figure 9, for the particular case of substrate oxidation. Accordingly, the electron is transferred from the substrate \(S\), to the cofactor \((\text{CF})_{\text{Ox}}\), which is permanently or temporarily bound to the enzyme backbone. The reduced cofactor is thereafter reoxidized by a suitable electron acceptor, \(A_1\).

Several transduction procedures have been proposed. The first involves the electrode reaction of the natural electron acceptor, \(A_1\), or its product, \(A_2\). Alternatively, an artificial mediator that shuttles the electrons from the prosthetic group of the enzyme to the electrode, through a regenerative process, may substitute the natural electron acceptor. Finally, it was attempted to perform the direct (nonmediated) electron transfer from the prosthetic group of the enzyme to the electrode. In this way, the electrode assumes the role of the cosubstrate \(A_1\). It is sometimes claimed that only this latter case truly belongs to bioelectrocatalysis,\(^ {147,148}\) although such a sharp distinction in terminology overshadows some of

---

Figure 9 Simplified scheme of an enzymatic amperometric sensor.
the practical advantages. Any of the above three methods can be the basis for the transduction process.

4.2 Main Classes of Enzymes Used for Amperometric Sensors

Oxidases contain a redox cofactor that accepts electrons from the substrate and makes use of molecular oxygen as a reoxidation agent (electron and hydrogen ion acceptor, \(A_1\) in the catalytic cycle). A typical example is the glucose sensor,\(^{(149)}\) which is based on glucose oxidation by molecular oxygen catalyzed by GOD (Scheme 3). Here FAD (flavin adenine dinucleotide) represents the prosthetic group of GOD, formally acting as a cofactor.

\[
\begin{align*}
\beta-D\text{-Glucose} & \rightarrow \beta-D\text{-Glucono-1,5-lactone} \\
\text{GOD/FAD} & \rightarrow \text{GOD/FADH}_2 \\
\text{H}_2\text{O}_2 & \rightarrow \text{O}_2
\end{align*}
\]

Scheme 3

The transduction may be performed by monitoring either the concentration of \(\text{O}_2\) (cathodic reaction) or that of \(\text{H}_2\text{O}_2\) (anodic reaction).\(^{(150)}\) Very often, this kind of sensor is said to be unmediated, because no artificial mediator is involved. However, from a mechanistic standpoint, the term “unmediated sensor” is more appropriate for that involving direct electron transfer between enzyme and electrode. The detection of either \(\text{O}_2\) or \(\text{H}_2\text{O}_2\) enjoys outstanding practical applications, but suffers some drawbacks that arise from interference by the electroactive compounds that are usually present in biological samples (ascorbic acid, glutathione, uric acid). In addition, these procedures are dependent on the pH and the oxygen content in the sample, and require additional manipulations (such as sample dilution with an oxygen-saturated buffer). Hence, artificial mediators are alternatively used to shuttle the electrons from the enzyme to an electrode. A typical example is represented by ferrocene (bis(\(\eta^5\)-cyclopentadienyl) iron) or its derivatives, which can be localized on a graphite foil in order to shuttle electrons from GOD to the electrode (Figure 10).\(^{(151-153)}\) Ferrocene electrochemical oxidation is a reversible process that occurs at a low electrode potential, thus preventing the disturbing electrode reaction.

Dehydrogenases are enzymes that carry out their catalytic function with the help of an electron acceptor other than \(\text{O}_2\). Nicotinamide adenine dinucleotide, (NAD\(^+\)/NADH) or nicotinamide adenine dinucleotide phosphate (NADP\(^+\)/NADPH) are low molecular redox cofactors that can accept (or donate, respectively) two electrons and a proton. A distinct class includes dehydrogenases acting on \(\text{CHOH}\) groups (such as lactate dehydrogenase or glucose-6-phosphate dehydrogenase), according to Equation (31):

\[
\text{NAD}^+ + \text{RR'CH–OH} \rightarrow \text{NADH} + \text{RR'C}=\text{O} + \text{H}^+ \tag{31}
\]

Here, NAD(P) acts as a cosubstrate, i.e. it is temporarily bound to the enzyme molecule jointly with the substrate in order to perform the chemical conversion of the latter, whereas the redox regeneration of the factor occurs in the solution phase, after leaving the enzyme molecule. This characteristic represents a major advantage from the standpoint of coupling the enzymatic reaction with the electrochemical transduction process.

When using such enzymes, the transduction can be performed by the electrochemical oxidation of NAD\(^+\), either by mediated electron transfer\(^{(152)}\) or directly on organic salt electrodes.\(^{(152,154)}\) Direct oxidation of NAD\(^+\) on metal or carbon electrodes requires a high overvoltage and is disturbed by interference and secondary processes.

Over 250 enzymes belongs to this class, thus offering a wide range of analytical applications based on NAD(P) electrochemistry. The retention of the cofactor in the reaction layer, either by chemical immobilization or by an exclusion principle, is essential because of its solubility in water.
Peroxidases are redox enzymes that can shuttle electrons to hydrogen peroxide (or small organic peroxides) from electron donors. The most common is horseradish peroxidase (HRP), which can accept electrons from virtually any reducing agent, such as ferrocyanide, phenol, ortho- and para-phenylenediamines, ascorbate, iodide, or ferrocene. The use of peroxidases in conjunction with hydrogen peroxide-producing oxidases is well established in analytical chemistry, including the field of amperometric biosensors.\(^\text{141}\)

### 4.3 Configuration of the Enzymatic Amperometric Sensor

An enzyme amperometric sensor includes most of the features of a CME (section 3). The main problems when designing an enzyme sensor are concerned with the selection of the enzyme itself, the electrode material, additional reagents such as the mediator, and the procedures for the immobilization of enzyme and reagents. These problems are interrelated and must be dealt with in an integrative way, taking into account the expected figures of merit: sensitivity, the shape of the response function, the extent of the dynamic range, response time, and robustness.

Carbon is often the preferred electrode material, either in the form of carbon paste\(^\text{155}\) or as a screen-printed electrode.\(^\text{120,141,156}\) It is sometimes convenient to use a CME as a transducer instead of a plain electrode. For example, phthalocyanine-modified carbon electrodes are very convenient for the electrocatalytic detection of hydrogen peroxide produced in oxidase-catalyzed processes (e.g. glucose or uric acid sensors). Conducting organic salts, sometimes dubbed “organic metals”, are the materials of choice for performing direct electron transfer to or from some biogenic compounds. Their use brings about a substantial simplification in sensor configuration.\(^\text{154}\) Conducting organic salts are made by the combination of an electron donor with an acceptor. Such compounds are planar molecules with delocalized \(\pi\)-electron density, both above and below the molecular plane, and show a nonisotropic electrical conductance. A typical example in this class is the donor tetrathiafulvalene (TTF) combined with the acceptor TCNQ.

In addition to the obvious case of the mono-enzyme sensor, inclusion of several enzymes is sometimes advantageous for interference removal (using an interferent-specific enzyme), mediated transduction using two mediators coupled with appropriate enzymes, indirect determination by competing enzyme reaction, or signal amplification by substrate recycling (Table 2).\(^\text{157}\)

### 4.4 Immobilization Methods

Immobilization is a crucial step in preparing an enzymatic sensor. The purpose of this step is to produce an enzyme layer that is as thin as possible and to preserve the highest possible specific activity of the enzyme.

Any method of enzyme immobilization may be used to build up the sensing layer of an enzymatic sensor: immobilization behind a permselective membrane, covalent attachment to a membrane, entrapment in polymer gels, covalent cross-linking with bi- or multifunctional reagents, covalent coupling to a polymeric support or directly to the functionalized electrode surface.\(^\text{158 – 160}\) The use of carbon as an electrode material has promoted immobilization into organic phase composite structures (carbon paste, carbon cement, carbon epoxy resins\(^\text{134,137,141,155}\) or screen-printed layers\(^\text{141}\)). Either mono- or multilayers can be prepared by enzyme binding to the self-assembled monolayer of a functionalized thiol.\(^\text{161,162}\)

Electropolymerized films\(^\text{163 – 166}\) represent a very attractive way of preparing the enzyme layer as the polymers provide a favorable microenvironment for the enzyme. The preparation procedure is straightforward and easily monitored by the electrochemical parameters (sections 3.3 and 3.6). In addition, an electronically conducting polymer also can perform coupling of the electron transfer between the molecular species and the electrode.

**Kinetic Determinations**
Either entrapment of the enzyme during the electrochemical preparation of the polymer film or covalent binding to a functionalized polymer layer may be employed as the immobilization procedure. The second, multistep method is more flexible and offers more possibilities for securing the expected properties to the enzyme-containing modifier film. Alternatively, it is possible to perform electrochemical copolymerization of the plain monomer (e.g., pyrrole) and the enzyme-bound monomer.

Some changes in enzyme properties due to immobilization may occur. Hence, the evaluation of some parameters (such as recovery of enzyme activity, effectiveness factor, enzyme loading, sensor response and extension of the linear range, pH and temperature effects) enables the effectiveness of the immobilization method to be assessed.\(^{(160)}\)

### 4.5 Redox Mediators for Amperometric Enzymatic Sensors

The use of a mediator makes the transduction process virtually independent of the ambient conditions and, simultaneously, shifts the working electrode potential to a convenient range, where the occurrence of a disturbing electrode reaction is less probable. An effective mediator is stable in both the oxidized and reduced forms; it should react rapidly with the enzyme and it should also exhibit a fast and reversible electrode reaction, with a low and pH-independent overpotential. The most frequently used artificial mediators include ferrocenes, hexacyanoferrate, phenoxazines, phenothiazines and phenazines, quinone/hydroquinone, TTF, and TCNQ.\(^{(120,146,152,155)}\)

Electropolymerized films offer a very convenient alternative for the integration of redox mediators in the modifier layer. Negatively charged modifiers (ferro/ferricyanide, ferrocene carboxylate, and hydroquinonesulphonate) may be entrapped as counterions in electronically conducting polymers. The poor long-term stability of such systems, due to mediator leakage, has prompted the use of redox polymers (section 3.3) as the immobilization environment for the enzyme.\(^{(164,165)}\) In this case, the polymer chain has to exhibit some flexibility so as to allow redox groups to reach an enzyme site.

### 4.6 Sensor Response: Modeling Enzyme Electrode Processes

A linear response over a broad concentration range is the ideal for any kind of sensor. Nevertheless, at least one step in the reaction sequence, namely the enzyme-catalyzed reaction, obeys a nonlinear kinetic equation and the situation is even more complicated in the case of the mediated electron transfer and multi-enzyme sensors. Consequently, careful optimization of sensor configuration, using both empirical and theoretical approaches, is essential for good performance. Generally, the electrode reaction, which represents the transduction process, is carried out with a sufficiently high overvoltage to make it very fast and kinetically irrelevant. The linear response occurs as a result of the mass transfer control of the overall reaction kinetics. Diffusion of the substrate or intermediate products through permselective membranes, or within the enzyme layer, could grant the appropriate mass transfer limitation.

The modeling of bioelectrocatalytic sensors is closely connected to the more general problem of mass transfer processes accompanied by reactions catalyzed by immobilized enzymes, a topic belonging to bioengineering.\(^{(167)}\) Owing to the variety of sensor configurations, a general theoretical treatment is not possible. However, some general strategies have been outlined.\(^{(168-171)}\)

In common with electrochemical kinetics, either mathematical analysis (using some numerical procedures) or digital simulation can be used to model the sensor process (see section 2.1.1). The most simple case is homogeneous mediation, which shows the characteristics of the EC mechanism (section 2.1) for the limiting case of very fast enzyme–substrate kinetics. This may be useful in preliminary investigations, but the actual sensor needs enzyme immobilization, and a series of additional factors must be considered: the number of enzyme reactions (Table 2); the number of layers (either reactive or protective); the kinetics of the enzyme reaction; the occurrence of either the steady state or transient behavior; the nature of the electroactive compound involved in the transduction process; and the required overvoltage. It is usually assumed that the diffusion proceeds along a single axis (planar diffusion) and obeys Fick’s laws. It is clear that modeling the processes occurring in enzyme electrodes is not an easy task, but it provides substantial rewards – a better understanding of the mechanism and kinetics operating in the system, and a logical basis for the design and optimization of the sensor.

### 4.7 Examples of Applications

Amperometric enzymatic sensors represent the most successful class of biospecific sensors,\(^{(120,137,141,155,172,173)}\) due mostly to the direct coupling of the recognition and transduction processes. They encompass the benefits of the dynamic electrode processes, such as linear response over a wide concentration range and the possibility of tuning the selectivity by the electrode potential.

The technological aspects of sensor production are an important area of research. It must be pointed out that an amperometric sensor is actually an electrochemical cell that needs, in addition to the sensing device, a reference electrode and, sometimes, an auxiliary electrode for operation in a three-electrode configuration. Microelectronics enables facile fabrication of the sensor, even for single-use application or at the micro scale, for in vivo measurements.[174,175] The use of microorganisms or tissue instead of isolated enzymes may achieve both operational and practical advantages.[155]

The applications of amperometric enzyme sensors encompass health care, the food and fermentation industries, defense, and environmental monitoring.[176] Glucose monitoring in blood is the first and still most widely used application, but other low-molecular-weight substances are currently determined by commercially available enzymatic sensors (Table 3).

5 CONCLUSIONS

Catalytic electrochemical processes may be used for analytical purposes either by adding the appropriate reagents to the sample solution or by including them in the structure of a CME. In the first case, the advantages of electrocatalysis are conveniently exploited using general-purpose devices such as the many versions of mercury electrodes. In the second case, it is possible to develop a specialized chemical sensor for field applications, single-use sensors, or detectors for the analysis in flowing fluids (flow injection analysis, liquid chromatography). Microdevices (UMEs, microchips) enable electrocatalysis-based sensors to perform analyses on very small sample volumes, in vivo analysis, or for detection in capillary electrophoresis. Analytical applications encompass a large variety of substances – from metal ions and simple inorganic species to various organic species, and many essential biological compounds.

LIST OF SYMBOLS

- $A$: electrode area
- $a = nFv/RT$: dimensionless sweep rate in LSV for a reversible electrode reaction
- $b = anFv/RT$: dimensionless sweep rate in LSV for an irreversible electrode reaction
- $c$: concentration of the species indicated by the subscript. The superscript “0” refers to bulk (equilibrium) concentration
- $D$: diffusion coefficient
- $E$: electrode potential (on the standard hydrogen electrode scale)
- $E^0$: standard redox potential for the redox couple shown by the subscript
- $E_{1/2}$: half-wave potential
- $E_c$: equilibrium electrode potential
- $E_i$: initial potential in LSV
- $F$: Faraday constant
- $h$: the height of the mercury level above the lower end of the mercury capillary electrode
- $i$, $i_c$, $i_d$, $i_0$, $i_k$: electrolytic current, catalytic current, diffusion current, exchange current, limiting current of the metal ion catalytic prewave
- $k$, $k_1$, $k_2$, $k_3$, $k_s$, $k_{QA}$: rate constant for Equation (7), homogeneous forward and backward rate constants, respectively, for the regeneration step, rate constant for the intramolecular electron transfer inside the catalyst–substrate adduct, acid ionization constant, equilibrium constant for the formation of the catalyst–substrate adduct
- $K_s$: conditional rate constant for the electrode reaction
- $K_{QA}$: stoichiometric coefficient of the electron in the electrode reaction
- $n$: square-wave period in SWV
- $q$: dimensionless potential sweep rate for LSV at a UME

Enzymatic Kinetic Determinations

Regina Hüttl
Technische Universität Bergakademie Freiberg, Germany

1 Introduction

Kinetic methods for analytical applications can be divided into noncatalytic and catalytic methods. Enzyme kinetic determinations are a special type of catalytic methods. Enzymatic reactions are used analytically to determine enzyme activities – for instance in the diagnosis of diseases, substrate concentrations in food industry and medicine and concentrations of effectors – for example in trace analysis. Due to the high selectivity of enzymatic analysis the importance of this method in various fields is growing rapidly. The widest use is observed in clinical chemistry and in food chemistry.

This article can only give a general survey of the great potential of enzymatic analysis, with references to more detailed literature.

Enzymatic reactions are characterized by some special features, explained after the introduction. The theoretical background for kinetic determination is the comprehension of the principles on enzymatic kinetics. In section 3 the simplest mechanism, outlined by Michaelis and Menten and several transformations of this equation will be described. In this section two kinetic parameters, enzyme activity and the Michaelis constant, will be introduced. Section 4 deals with substances, so called effectors, influencing the rate of an enzymatic reaction. Simple mechanisms of these effectors will be shown. The different methods for determination of substrates, enzymes and effectors, illustrated by many examples, are represented in section 5. While substrate concentrations can be determined using both ways, equilibrium or kinetic methods, the determination of enzymes and effectors can only be performed by kinetic approaches. In the last two sections the application of immobilized enzymes in flow systems and biosensor development will be shown.

1 INTRODUCTION

Kinetic methods are useful tools in analytical chemistry. The use of enzymes in kinetic-based determinations is widely applied for the analysis of many substances, for instance in medicine or the food industry, for the analysis of enzymes, especially enzyme activities in clinical diagnostics, and for the determination of inhibitors or activators of enzymes, i.e. trace analysis. The enzymatic analysis method combines the exceptional selectivity with high sensitivity. This article can only attempt a general survey of the enormous potential of the enzymatic analysis, with references to more detailed books or reviews.

At the beginning of this article the special features of enzymatic reactions are characterized and the theoretical background for the application of enzymatic catalysis, the comprehension of the principles on enzymatic kinetics, is described. The rate of the enzymatic reaction can be either increased or decreased by the effect of some substances known as activators or inhibitors, respectively. Simple mechanisms of the effectors are explained in section 4. Examples of the analytical application of enzymatic catalysis for the determination of substrates, enzymes and effectors are given. The use of immobilized enzymes in flow systems and biosensors is presented in the last, but not less interesting, two sections.
2 FEATURES OF ENZYMATIC REACTIONS

All enzymes are proteins produced by living cells that catalyze specific reactions with a high degree of efficiency. In the following the special features of enzymes will be represented, including some relevant information for their analytical uses.

2.1 High Specificity of Enzymes

Enzymes are very highly specific in their choice of substrate. Think of the ‘key-lock’ theory by Fischer or the ‘induced fit’ hypothesis, suggested by Koshland. Therefore, enzymes are unique analytical reagents. The ideal enzyme for analytical purposes would catalyze only one chemical reaction.

2.2 Temperature

Most enzymatic reactions are carried out within the physiological temperature range of 25–37 °C. As is known from other chemical reactions, there is an increase in reaction rate with temperature. In view of the fact that the enzyme is a protein, it becomes denatured above about 50 °C. Figure 1 shows a typical curve for the dependence of enzymatic activity on temperature. The optimum operating temperature differs from one enzyme to another. For enzymatic reactions it is very important to control the temperature during the measurement. The use of buffer is advisable. Extreme pH value leads also to denaturation of the protein. The proper choice of pH is especially important in enzyme assays with enzyme-coupled systems, because there can be different pH optima for the coupled enzymes.

2.3 pH Value

Most enzymes are very sensitive to changes in pH. The effect of pH is due to an alteration in the conformation of the protein structure or the ionization of the active site of the enzyme or substrate. As seen in Figure 2 there is an optimum in pH value (generally in the pH range of 5–7). Therefore it is very important to keep the pH value constant during the measurement. The use of buffer is advisable. Extreme pH value leads also to denaturation of the protein. The proper choice of pH is especially important in enzyme assays with enzyme-coupled systems, because there can be different pH optima for the coupled enzymes.

2.4 Cofactors

Many enzymes need the presence of a nonprotein component (molecular mass generally between $10^2$–$10^3$ g mol$^{-1}$), called cofactors, for catalytic activity. In this case, the inactive protein component is termed apoenzyme and the active enzyme, including cofactor, the holoenzyme. If the cofactor is an organic molecule it is called coenzyme. For analytical purposes, e.g. in photometric analysis, the coenzyme nicotinamide adenine dinucleotide (NAD) is widely used (see section 5.1). Other cofactors may be metal ions, e.g. zinc or iron ions. Their analytical importance is given in section 5.3.

2.5 Ionic Strength

Enzymatic reaction rates can be changed by the presence of some salts. The addition of small amounts of neutral salts may increase the solubility of a protein. Salts can cause changes in ionization of amino acid side chains. Therefore the choice of buffer recipe for any given pH is very important for the reaction rate and the mechanism of an enzymatic reaction.

3 REACTION MECHANISM AND KINETIC EQUATIONS

The following kinetic considerations are restricted to the classical approach by Michaelis and Menten. Deviations
from the hyperbolic dependence of the reaction rate on the substrate concentration will not be represented. Furthermore, in most cases only single substrate reactions are significant for the analytical application of enzymes.

### 3.1 Michaelis–Menten Equation

In the early 1900s two biochemists, Michaelis and Menten worked out a theory for the kinetic analysis of enzyme-catalyzed reactions. The simplified mechanism can be written as Equation (1):

$$
E + S \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} [ES] \overset{k_2}{\underset{k_{-2}}{\rightarrow}} P + E
$$

where $E$ is the enzyme, $S$ the substrate, $[ES]$ the intermediate enzyme–substrate complex and $P$ the product(s). The $k$'s are the rate constants. The substrate concentration is much larger than the enzyme concentration so that the formation of $[ES]$ does not alter the substrate concentration. This reaction scheme has been treated both as pre-equilibrium\(^1\) and as a steady-state case.\(^2\)

Then, the Michaelis–Menten equation becomes Equation (2):

$$
\frac{-d[S]}{dt} = \frac{k_2[S][E_0]}{K_m + [S]}
$$

$K_m$ is the Michaelis constant, $[S]$ the substrate concentration and $[E_0]$ the total concentration of enzyme present. This expression shows the relationship between reaction rate and concentration of both substrate and enzyme. Equation (2) is the base of determination of substrate concentrations and enzyme activities.

Further on, we know that when the substrate concentration is very high, all the enzyme is present as the enzyme–substrate complex and the maximum rate $v_{\text{max}}$ is reached (enzyme saturation). Under these conditions we have Equation (3):

$$
v_{\text{max}} = k_2[E_0]
$$

We can substitute $v_{\text{max}}$ in Equation (2) and get Equation (4):

$$
\frac{-d[S]}{dt} = \frac{d[P]}{dt} = \frac{v_{\text{max}}[S]}{K_m + [S]} = v
$$

Equations (2) and (4) are only precisely valid in the case of the initial reaction rate $v_0$ (Equation 5):

$$
v_0 = \frac{v_{\text{max}}[S_0]}{K_m + [S_0]}
$$

For determinations of substrate concentration and enzyme activities we have to discuss two experimental possibilities:

1. $[S] \gg K_m$, thus the initial reaction rate $v_0$ is directly proportional to the enzyme concentration (Equation 6):

$$
v_0 = \frac{k_2[S_0][E_0]}{[S_0]} = k_2[E_0]
$$

Since $v_{\text{max}} = k_2[E_0]$, this attempt is commonly called saturation conditions.

2. $[S] \ll K_m$, thus the initial reaction rate $v_0$ is directly proportional to the substrate concentration, assuming the determination has been carried out under constant enzyme condition ($v_{\text{max}}/K_m = \text{constant}$) (Equation 7):

$$
v_0 = \frac{k_2[S_0][E_0]}{K_m} = \frac{v_{\text{max}}[S_0]}{K_m}
$$

When the rate of an enzymatic reaction $v$ is plotted against the substrate concentration $[S]$ a hyperbolic curve is obtained (see Figure 3). Enzyme-catalyzed reactions show a first-order dependence of the reaction rate at low concentrations of substrate and as the substrate concentration rises, the reaction rate approaches a maximum rate $v_{\text{max}}$, the enzyme saturation. This is the region of zero-order kinetics. At intermediate substrate concentrations, the relationship between the reaction rate and the substrate concentration follows neither first-order nor zero-order kinetics.

### 3.2 Integrated Michaelis–Menten Equation

Mentioned in section 3.1, the Michaelis–Menten equation is only precisely valid in the case of the initial reaction rate $v_0$, i.e. when the substrate concentration $[S] = [S_0]$, or when less than 5% of $[S]$ is converted to product $P$.\(^3\) Under many experimental conditions it

![Figure 3](image-url)
may not be feasible to restrict the reaction extent to 5% or less. In contrast to this, the integrated form of the Michaelis–Menten equation is valid over the entire course of the reaction. This we can write as Equation (8):

$$[S] = [S]_0 - [P]$$  

Equation (9):

$$[P]$$ and $$[S]$$ are the product or substrate concentration at time $$t$$.

Insertion of Equation (8) into Equation (4) leads to Equation (9):

$$v = \frac{d[P]}{dt} = \frac{v_{\text{max}} ([S]_0 - [P])}{[S]_0 - [P] + K_m}$$  

Integration of Equation (9) between time $$t = 0$$ and any time $$t$$ and between the corresponding two product concentrations 0 and $$[P]$$ leads to Equation (10):

$$t = \frac{K_m}{v_{\text{max}}} \ln \frac{[S]_0}{[S]_0 - [P] + \frac{[P]}{v_{\text{max}}}}$$  

Equation (10) presents the relationship between product concentration $$[P]$$ and time $$t$$. Moreover, Equation (10) can be rearranged to give Equation (11):

$$t = \frac{K_m}{v_{\text{max}}} \ln \frac{[S]_0}{[S]_0 + \frac{[S]_0 - [S]}{v_{\text{max}}}$$

The application of Equation (10) for the determination of $$K_m$$ and $$v_{\text{max}}$$ (or the enzyme activity) is described in section 3.4.

### 3.3 Michaelis Constant and Enzyme Activity

The Michaelis constant, $$K_m$$, is defined as the substrate concentration at half the maximum reaction rate (Equation 12): 

$$v = \frac{[S]_{\text{max}}}{2[S]} = v_{\text{max}} \frac{2}{2}$$

Thus $$K_m$$ will have the same units as the substrate concentration. Using the two methods for treatment of enzyme-catalyzed reaction Equation (1), one can obtain Equations (14) and (16):

1. Michaelis–Menten assumption of equilibrium between substrate, enzyme and substrate–enzyme complex (pre-equilibrium or rapid equilibrium), $$k_2 \ll k_{-1}$$, Equation (13):

$$E + S \underset{k_2}{\overset{k_{-1}}{\rightleftharpoons}} [ES] \rightarrow P + E$$  

$$K_m = K_s = \frac{k_{-1}}{k_1}$$

$$K_s$$ = dissociation constant for the enzyme–substrate complex

2. For Equation (15):

$$E + S \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} [ES] \overset{k_2}{\rightarrow} P + E$$  

Briggs–Haldane steady-state assumption, Equation (16):

$$K_{II} = \frac{k_{-1} + k_2}{k_1}$$

The Briggs–Haldane assumption is the more general one, eliminating the requirement for the enzyme–substrate complex to be in equilibrium with free enzyme and free substrate. Thus, $$K_m$$ is a dynamic or pseudo-equilibrium constant. $$K_m$$ is a constant for a given substrate under well-defined experimental conditions such as temperature, buffer, pH and ionic strength. It represents the affinity between the substrate and the enzyme. A small value of $$K_m$$ means a high affinity between substrate and enzyme and the enzyme becomes saturated at small concentrations of substrate. Michaelis constants for enzyme usually range from $$10^{-2}$$ to $$10^{-5}$$ mol L$$^{-1}$$. For enzymatic analysis methods a small value of $$K_m$$ results in a very limited linear concentration range in calibration graphs based on initial reaction rate as a function of substrate concentration. If we know $$K_m$$, we can adjust the experimental conditions for determining substrate concentration or enzyme activity (see section 3.1). The activity of an enzyme preparation varies from one source to another, since the purification of the enzyme is in general not complete. Because of this, in most preparations the actual molar concentration of enzyme is unknown, and therefore the quantity generally used to express the enzyme activity is the unit, defined in terms of reaction rate.

One international unit (U) of enzyme is defined as that amount catalyzing the conversion of micromole substrate to product in 1 minute under optimal conditions.

The declaration of the optimal conditions has to include the temperature (usually 25 or 30°C), pH value and buffer system. For determining the enzyme activity the substrate concentration should be sufficient for saturation. The Nomenclature Commission of the International Union of Biochemistry has recommended the use of the katal (kat), which differs from the definition of the unit through the declaration of 1 mole substrate and time of 1 second:

$$1 \text{ kat} = 6 \times 10^7 \text{ U}$$

The specific activity of an enzyme preparation is the number of units per mg protein or in the case of solution or suspension one can declare the number of units per
milliliter. If the molecular mass of an enzyme is known it is possible to express the molecular activity in units per µmol enzyme.

In Palmer⁴ one can also find the terms: turnover number $k_{cat}$ and catalytic efficiency $k_{cat}/K_m$. The constant $k_{cat}$ is defined in Equation (17):

$$k_{cat} = \frac{v_{max}}{[E]_0}$$  \hspace{1cm} (17)

If the enzyme concentration is known the ratio $k_{cat}/K_m$ is a good measure for catalytic efficiency of an enzyme.

### 3.4 Determination of Kinetic Parameters

The determination of the kinetic parameters $v_{max}$ and $K_m$ can be carried out by measuring the initial reaction rate as the substrate concentration is varied. If experimentally possible, the substrate concentration should be varied in the range from $K_m/10$ to $10K_m$. In the literature there are some linearization procedures (see Figure 4):

#### 3.4.1 The Lineweaver–Burk Plot

The linearization of the Michaelis–Menten equation Equation (5) by Lineweaver and Burk (Figure 4a) is the most widely and traditionally used method. It is a double reciprocal plot (Equation 18):

$$\frac{1}{v_0} = \frac{K_m}{v_{max}} \frac{1}{[S]_0} + \frac{1}{v_{max}}$$  \hspace{1cm} (18)

From the slope ($K_m/v_{max}$) or the intercept on the ordinate ($1/v_{max}$) or the intercept on the abscissa ($-1/K_m$) one can obtain the two kinetic parameters. But such a double-reciprocal method has a strong distorting effect on the data.

#### 3.4.2 The Hanes Plot

The plot $[S]_0/v_0$ versus $[S]_0$ due to Hanes and Woolf (Figure 4b) is much better with regard to this effect. The data are more evenly weighted over the whole concentration range. Equation (18) may be rearranged to give Equation (19):

$$\frac{[S]_0}{v_0} = \frac{1}{v_{max}}[S]_0 + \frac{K_m}{v_{max}}$$  \hspace{1cm} (19)

From this linear plot the parameters $K_m$ and $v_{max}$ can be calculated.

#### 3.4.3 The Eadie–Hofstee Plot

The Eadie–Hofstee plot (Figure 4c) is the straight line graph $v_0$ versus $v_0/[S]_0$, Equation (20):

$$v_0 = -K_m \frac{v_0}{[S]_0} + v_{max}$$  \hspace{1cm} (20)

Both plots (Eadie–Hofstee plot and Hanes plot) are less frequently used, but they are better suited for kinetic determination than the Lineweaver–Burk plot.

#### 3.4.4 Integrated Michaelis–Menten Equation

All above-mentioned methods require the measurement under initial conditions. If it is not possible to fulfill this requirement – for example, it may be difficult to determine very low concentrations of product – one can use the integrated Michaelis–Menten equation (see section 3.2) for the determination of $v_{max}$ and $K_m$. The linear transformation of Equation (10) gives Equation (21):

$$\frac{t}{[P]} = \frac{K_m}{v_{max} [P]} \ln \frac{[S]_0}{[S]_0 - [P]} + \frac{1}{v_{max}}$$  \hspace{1cm} (21)

The Michaelis constant and maximum rate can be determined by measuring the concentration of product several times during the reaction and plotting the respective values as shown in Figure 5.
4 MODIFYING THE KINETIC BY EFFECTORS

The rate of the enzymatic reaction can be either increased or decreased by effectors. While activators accelerate the enzymatic reaction, inhibitors reduce the rate of the enzymatic reaction. For this reason all enzymatic analyses of effectors involve the determination of reaction rates (different kinetic methods are described in section 5 or in P´erez-Bendito and Silva).

4.1 Activators

An activator increases the catalytic effectiveness or the activator transforms the inactive apoenzyme (see section 2.4) to the active holoenzyme. Various substances can activate the same enzyme. In consequence, there is a lack of specificity for determination of individual ions.

The course of the initial rate in the presence of an activator is similar to that of substrate concentration, discussed in section 3.1. At low activator concentration one can find that the initial rate is directly proportional to the concentration of the activator. But at higher concentrations the enzyme is maximally activated (similar to the enzyme saturation at high substrate concentrations) and the initial rate becomes independent of the concentration of the activator. Consequently the determination of effectors has to be carried out at low levels of activator concentrations. Examples for the analytical application, e.g. the determination of metallic ions, are given in section 5.3.

4.2 Inhibitors

Inhibitors are substances which cause a decrease in the rate of a catalytic reaction. The enzyme inhibition can be either reversible or irreversible. The characteristic of the reversible inhibition is the equilibrium between enzyme and inhibitor. In contrast, the irreversible inhibitor binds covalently to the enzyme. Seen from Figure 6, the enzymatic reaction rate can be influenced by several substances. We distinguish:

- substrate inhibition
- product inhibition
- competitive inhibition (formation of enzyme–inhibitor complex EI)
- uncompetitive inhibition (formation of enzyme–inhibitor–substrate complex EIS)
- noncompetitive inhibition (equal affinity of formation of EI and EIS).

4.2.1 Competitive Inhibition

The inhibitor competes with substrate (or coenzyme) for the active centre of the enzyme. Since the inhibitor forms the enzyme-inhibitor complex, the proportion of free enzyme will be reduced and the rate of the enzymatic reaction decreases. Hence, the competitive inhibition can be made ineffective by an excess of substrate. In most cases we find that the chemical structure of the substrate is similar to that of the competitive inhibitor. Figure 7(a) shows the Lineweaver–Burk plot of the competitive inhibited enzyme reactions. The curves increase in slope (increase in $K_m$), while the intercept on the $1/v_0$ axis remains constant. The maximum rate in the presence of a competitive inhibitor is always equal to $v_{max}$ of the uninhibited reaction.

4.2.2 Uncompetitive Inhibition

The inhibitor binds only to the enzyme–substrate complex ES. Figure 7(b) shows the Lineweaver–Burk plot of the uncompetitive inhibited enzyme reaction. The uncompetitive inhibitor decreases $v_{max}$ and $K_m$. The decrease of $K_m$ means an apparent increase in the affinity of the enzyme for its substrate.

4.2.3 Noncompetitive Inhibition

The inhibitory mechanism, where the inhibitor binds with equal affinity to both the enzyme and the enzyme–substrate complex, is called noncompetitive
inhibition. Noncompetitive inhibitors bind to the enzyme at a site that is distinct from the substrate binding site.\(^6\)

Hence, this type of inhibition cannot be overcome by increasing the substrate concentration. Figure 7(c) illustrates that the noncompetitive inhibition leads to an apparent decreasing of \(v_{\text{max}}\), while the Michaelis constant is not altered.

### 4.2.4 Substrate Inhibition

As represented in section 3.1, the initial rate of an enzyme reaction increases with increasing initial substrate concentration to a maximum value \(v_{\text{max}}\). But in some cases we can find a decreased initial rate at high substrate concentrations, seen in Figure 8. There, an excess of substrate can inhibit its own conversion to product.

### 4.2.5 Product Inhibition

The product of some enzyme reaction can also be an inhibitor. The product may bind to the active site of the enzyme. Consequently the active site is blocked and cannot bind further substrate molecules. Thus, the rate of the enzyme reaction decreases.

---

**Figure 7** Lineweaver–Burk plots for (a) competitive inhibition; (b) uncompetitive inhibition; (c) noncompetitive inhibition.

**Figure 8** Substrate inhibition.

The represented types of enzyme inhibition are not complete. More detailed information can be found in Segel.\(^{7}\) Examples for analytical application are given in section 5.3.

## 5 ENZYMATIC DETERMINATIONS

The methods to be used in monitoring enzyme-catalyzed reactions are dictated by the chemistry and physical chemistry of the reaction. We can distinguish three classes:

- spectrophotometric
- electrochemical
- calorimetric.

In the following only some typical examples of the determination of substrates, enzymes and effectors, using different monitoring techniques, are represented. In the literature one enzyme plays an exceptional role – glucose oxidase (GOD) as analytical reagent is the most widely used enzyme.\(^{8}\)

### 5.1 Determination of Substrates

The substrate determination can be carried out by both, equilibrium and kinetic approaches. The *equilibrium method*, also called *end-point method*, means the measurement of the total change, almost all of the substrate being converted to product. The analysis can be performed by measuring the appearance of product or the disappearance of substrate. To ensure rapid progress towards equilibrium, the concentration of the used enzyme should be high. Any other substances necessary for enzyme-catalyzed reaction, such as cofactors (coenzyme or metal ions), should be in excess, so that they do not limit the reaction. Because of the possible side reactions or instability of products or reactants, the enzyme reactions are often not stoichiometric with respect to the substrate concentration. Therefore the calibration curves must be prepared under the selected experimental conditions. There, the measured quantity is related to known concentrations of substrates.
The kinetic determinations of substrates should be carried out under conditions where the concentration of substrate is in the range to fulfill the first order circumstances (\([S_0] \ll K_m\), see Equation (7) section 3.1). In Christian\(^9\) one can find three forms:

- measure the time required for the reaction to convert a certain amount of substrate or form a certain amount of product
- measure the amount of substrate converted or product generated in a given time and
- continuous measurement of substrate or product concentration as a function of time, or initial slope method.

The initial slope method means that the change in some physicochemical parameters (absorption, pH or temperature), related to the change of concentration, are plotted as a function of time. Kinetic methods are generally more rapid than equilibrium methods, but also more sensitive to enzyme effectors.

Analytical applications of enzyme-catalyzed reactions for determining substrates are widely used in many fields. Table 1 gives some examples for applications in food industry, medicine and environmental analysis; further pertinent information can be found in Bergmeyer.\(^10\)

As seen from Table 1, many reactions with dehydrogenases need the coenzyme NAD. The NADH and the oxidized form (NAD\(^+\)) differ in their ultraviolet absorption spectra. NAD does not adsorb photons in the 340 nm region of spectra, whereas its reduced form does.

Such differences in absorption spectra of products, substrates or other reactants are widely used in the

As an example, the amount of NADH produced according to Equation (22) is a measure of the amount of acetaldehyde present in wine or beer.\(^\text{[11]}\)

\[
\text{Acetaldehyde} + \text{NAD}^+ + \text{H}_2\text{O} \xrightarrow{\text{AI-DH}} \text{acetic acid} + \text{NADH} + \text{H}^+ \tag{22}
\]

(AI-DH = aldehyde dehydrogenase, E.C. 1.2.1.3, 9028-86-8)

Moreover, NADH is used as a coupling agent. Two or more reactions occur in sequence. At the end of such a sequence, NAD\(^+\) is generated or consumed. For example, the determination of creatinine or creatine is represented by Equation (23–26):

\[
\text{Creatinine} + \text{H}_2\text{O} \xrightarrow{\text{CAH}} \text{creatinine} \tag{23}
\]

\[
\text{Creatine} + \text{ATP} \xrightarrow{\text{PK}} \text{creatine phosphate} + \text{ADP} \tag{24}
\]

\[
\text{ADP} + \text{phosphoenolpyruvate} \xrightarrow{\text{PK}} \text{ATP} + \text{pyruvate} \tag{25}
\]

\[
\text{Pyruvate} + \text{NADH} + \text{H}^+ \xrightarrow{\text{LDH}} \text{L-lactate} + \text{NAD}^+ \tag{26}
\]

The amount of NADH consumed is stoichiometric with the amount of creatine or creatinine.\(^\text{[12]}\)

(CAH creatinine amidohydrolase, E.C. 3.5.2.10, 9025-13-2

CK creatinine kinase, E.C. 2.7.3.2, 9001-15-4

PK pyruvate kinase, E.C. 2.7.1.40, 9001-59-6

LDH E.C. 1.1.1.27, 9001-60-9

ADP adenosine diphosphate

ATP adenosine triphosphate

The hydrogen peroxide is electrochemically oxidized at the platinum cathode, Equation (28):

\[
\text{H}_2\text{O}_2 \longrightarrow \text{O}_2 + 2\text{H}^+ + 2\text{e}^- \tag{28}
\]

The current obtained is proportional to the glucose concentration (principle of Clark oxygen electrode).

The substrate concentration of such an oxidase-catalyzed reaction (Equation 27) can also be measured with an iodide-selective electrode\(^\text{[14]}\), Equation (29):

\[
\text{H}_2\text{O}_2 + 2\text{I}^- + 2\text{H}^+ \xrightarrow{\text{Mo(VI)}} \text{I}_2 + 2\text{H}_2\text{O} \tag{29}
\]

The decrease in iodide concentration is proportional to the substrate concentration, for instance glucose.

\[
\text{Leuco dye} \xrightarrow{\text{Peroxidase}} \text{Dye} \tag{30}
\]

In H\(_2\)O\(_2\)-generating systems, substrate concentrations can also be determined by using indicator reactions.\(^\text{[15]}\) One example is the determination of glucose with indicator reactions based on the peroxidase (E.C. 1.11.1.7, 9003-99-0) catalyzed oxidation of single chromogen (Equation 30).

An interesting way to increase the sensitivity of enzymatic substrate determinations is amplification by cycling of enzyme-catalyzed reactions. The principle based on the following scheme:

The substrate to be determined is converted by an initial enzyme to a product. This product is the substrate of a second enzyme, which regenerates the substrate. Therefore it can be converted by the first enzyme again and thus the cycle is reinitiated.

A typical example is the determination of NADP by a cycling of NADPH between two enzyme reactions.\(^\text{[16]}\)

5.2 Determination of Enzymes

Since enzymes are catalysts, affecting the rate of the reaction, not the equilibrium, their activity must be
measured by a kinetic method. The kinetic determination of enzymes should be carried out under conditions where the substrate concentration is in excess and all other substances which influence the rate of reaction are present in fixed and non-limiting concentrations. Then the value of $K_m$ can be neglected and the rate of the enzyme reaction depends only on the enzyme concentration (zero order conditions, see Equation (6) section 3.1). The three possible forms of determination are identical to the kinetic determination of substrates (see section 5.1).

Because of the influence on the enzyme activity (see section 2), the pH value and the temperature have to keep constant during the measurement.

Enzyme determinations are chiefly applied in clinical diagnostics, food industry and monitoring biotechnological processes. Table 2 shows a selection of interesting enzymes; further information is found in Bergmeyer.

As seen in the Table 2, spectrophotometric monitoring of NADH consumption as a function of time can be used to determine the enzyme activity of various enzymes.

The determination of amylase activity by measuring the produced reducing sugar as a function of time is an example of the application of the colorimetric method. An alkaline solution of 3,5-dinitrosalicylic acid and K-Na-tartrate is used as a chromogenic reagent. Another, even more simple, case of colorimetric method is the determination of the AP activity. There the formation of the yellow $p$-nitrophenol under alkaline conditions is measured.

Furthermore the pH-stat method is used to determine enzyme activities. Monitoring enzyme reaction by pH-stat method means that the pH is maintained at constant value by frequent addition of alkali. The rate at which the base is added is proportional to the enzyme activity. The determination of lipase activity in serum (Equation 31) is a typical example.

Triglyceride + $\text{H}_2\text{O} \rightarrow \text{diglyceride} + \text{fatty acid} \ (31)$

AP, alkaline phosphatase.
The produced fatty acid is neutralized by counter titration with NaOH. Normally olive oil is used as the substrate. More examples for enzyme determinations and automated pH-stat systems can be found in Gul et al.\(^{(19)}\)

Among the pH-stat systems, other electrochemical methods such as conductometry (change in overall ionic mobility is measured as a function of time), amperometry (O\(_2\) consumption or H\(_2\)O\(_2\) production is measured as a function of time) or ion-sensitive electrodes (see section 5.1) are also usable.

The calorimetric determination of invertase activity is described.\(^{(20)}\) The sucrose hydrolysis shown in Equation (32) was performed in an isoperibolic calorimeter (invertase, E.C. 3.2.1.26, 9001-57-4). The kinetic evaluation of the calorimetric curves qualified to determine the enzymatic activity.

\[
sucrose + H_2O \xrightarrow{\text{inversion}} \text{glucose} + \text{fructose} \quad (32)
\]

Finally, electrophoresis is an important method for determining the catalytic activity of nuclease.\(^{(21)}\)

### 5.3 Determinations of Effectors

The rate of the enzyme reaction can be influenced by various substances (see section 4). This characteristic feature of enzyme reactions can be used for analytical purposes, the determination of activators and the determination of inhibitors. These methods are especially important in trace metal determinations, since in most cases only a single oxidation state of metal is determined. The enzymatic analysis based on activator effects is not as frequently used as the determination based on inhibitor effects. Because effectors influence the kinetic of the enzyme reaction, their determination requires the monitoring of enzyme reactions as a function of time, i.e. kinetic determinations.

#### 5.3.1 Activators

Many enzymes require for their catalytic activity cofactors (see section 4.1) or the ‘true substrate’ (SA), where A is generally a metal ion.\(^{(22)}\) For example, reactions involving ATP require Mg\(^{2+}\) ions to form MgATP\(^{2-}\) (A = Mg\(^{2+}\)).

For instance, the amounts of magnesium can be determined according to Equation (33):

\[
luciferase \rightarrow \text{oxy Luciferin} + ADP + PO_4^{3-} \quad (33)
\]

The formation of oxy Luciferin is combined with green chemiluminescence. Trace amounts of magnesium (ppb levels) can be determined.\(^{(23)}\)

Other inorganic substances combine with the enzyme at a specific activator site. This activation may be essential or nonessential. Table 3 shows some examples of activation by inorganic substances. Pertinent information on the requirement or effectiveness of some substances for the catalytic activity of multitude of enzymes can be found in Schomburg and Salzmann.\(^{(24)}\) These details are important for the application of activator effects for analytical purposes.

The experimental procedure of trace element analysis, using metallo-enzymes (specific metal ions are located at the active centers of the enzyme) is characterized by the removal of the metal ion from the holoenzyme (see section 4.1) by treatment with chelating agents (for instance EDTA). The resultant apoenzyme is catalytically inactive. The activator assay consists of the respective apoenzyme, its natural substrate, and a sample containing the metal ion. Then the restoration of enzyme activity is proportional to the amount of metal ion in the sample. In this way trace amounts of metal ions can be determined. An example is the determination of zinc ions by using AP (Equation 34):

KINETIC DETERMINATIONS

4-nitrophenyl phosphate + H₂O

\[
\text{AP} \rightarrow 4\text{-nitrophenol} + \text{phosphate} \quad (34)
\]

The enzyme activity is determined by measuring the rate of release of 4-nitrophenolate ion (alkaline pH) at 410 nm in a recording spectrometer. The method is so sensitive that 0.5 ng zinc can be determined in small volumes (0.5 µl) of plasma.\(^{29}\)

Many enzymes require for their catalytic activity a specific coenzyme (see Table 4). At low concentrations of enzyme the degree of activation of such an enzyme is proportional to the concentration of coenzyme. That is in contrast with the assay for determining substrate concentrations (see section 5.1), where the coenzyme should be in excess.

For instance, ATP, an important intermediate in energy metabolism, can be determined by the following reaction scheme (Equations 35 and 36):

\[
\text{ATP} + \text{glucose} \xrightarrow{\text{HK}} \text{glucose-6-phosphate} + \text{ADP} \quad (35)
\]

\[
\text{G6PDH} \phantom{\xrightarrow{}} \text{glucono-1,5-lactone 6-phosphate} + \text{NADPH} \quad (36)
\]

\text{(HK Hexokinase, E.C. 2.7.1.1, 9001-51-8)
G6PDH glucose 6-phosphate dehydrogenase, E.C. 1.1.1.49, 9001-40-5}

The reaction can be monitored by the formation of NADPH spectrophotometrically at 340 nm.

5.3.2 Inhibitors

In the literature one can find a variety of enzyme inhibitors. Table 5 shows a selection of well-known inorganic and organic inhibitors. The relative effect on enzyme activity of different substances is characterized by the IC\(_{50}\) value. The IC\(_{50}\) value is the inhibitor concentration giving 50\% inhibition.\(^{30}\) Several analytical methods have been developed based on the inhibition of enzyme reactions.

As seen from Table 5, one enzyme often has various inhibitors. Therefore, investigations of inhibitor effects are not as practicable for single-component analysis as for determination of summary or group specific parameters. An example is the screening of pollutants in waste water. Furthermore, enzyme inhibition tests are suitable to preselect polluted samples.

In the following some examples for analytical application (see also sections 6 and 7) are represented. There is a variety of methods for determination of inhibitors, dictated by the physicochemistry of the enzyme reaction to be monitored.

The urease-catalyzed urea hydrolysis can be inhibited by various metal ions (see Table 5). The inhibitor effect is used for the screening of heavy metals in water. An example is the microtiter-plate urease inhibition assay
based on the determination of the released ammonia with an indophenol reaction. Highest sensitivity was found for 
\( \text{Hg}^{2+} \) (detection limit of 0.05 \( \mu \text{g L}^{-1} \)).

Pesticide pollution in water is a serious problem, especially for drinking water quality. The acetylcholinesterase (ACHE) inhibition test is a well-known method for the determination of organophosphorous acid esters and \( \text{N} \)-methyl carbamates. Photometric tests are widely used. The hydrolysis of acetylthiocholine by ACHE (E.C. 3.1.1.7, 9000-81-1) is measured (Equations 37 and 38):

\[
\text{acetylthiocholine} + \text{H}_2\text{O} \xrightarrow{\text{ACHE}} \text{thiocholine} + \text{CH}_3\text{COOH}
\]  
\text{thiocholine} + \text{dithiobisnitrobenzoate} \xrightarrow{} \text{thionitrobenzoate} \text{ (yellow dye)} \tag{37}

The entire inhibition effect, in comparison with the uninhibited ACHE, is given in paraoxon equivalent. \tag{38}

This inhibition effect can also be measured by amperometric detection (Equations 39–41):

\[
\text{acetylthiocholine} + \text{H}_2\text{O} \xrightarrow{\text{ACHE}} \text{choline} + \text{CH}_3\text{COOH}
\] \tag{37}

\[
\text{choline} + 2\text{O}_2 + \text{H}_2\text{O} \xrightarrow{\text{choline oxidase}} \text{betaine aldehyde} + 2\text{H}_2\text{O}_2
\] \tag{39}

\[
\text{H}_2\text{O}_2 \xrightarrow{\text{anodic oxidation}} \text{O}_2 + 2\text{e}^- + 2\text{H}^+
\] \tag{40}

\[
\text{O}_2 \text{gas} \text{is passed to a detector, where N-thionitrobenzoate (yellow dye) is oxidized to thionitrobenzoate,}
\] \tag{41}

\text{Hg}^{2+}

and other metals show that \( \text{As(III)} \)-ions inhibit the urea hydrolysis by competitive mechanism, while \( \text{As(V)} \)-ions do not inhibit the enzyme in the comparable concentration range. \tag{38}

For the evaluation of the potential of toxicological hazard the differentiation of arsenic content should be important.

6 IMMOLIZED ENZYMES FOR DETERMINATIONS IN FLOW SYSTEMS

In analytical chemistry the use of immobilized enzymes is rapidly increasing. The term immobilized enzymes stands for a preparation in which an enzyme is confined or localized in a relatively well-defined region. Enzymes may be immobilized by covalent bindings, by crosslinking, adsorption or entrapment within various matrices, for instance membranes or polymeric gels. Different techniques used for the immobilization of enzymes are described extensively. \tag{39,40}

Enzyme immobilization is an economical requirement, since an immobilized enzyme can easily separate from the reaction solution and becomes therefore reusable. Besides, immobilization frequently leads to an improvement of thermal and/or chemical stability of enzyme preparation in comparison to the soluble or native enzyme. On the other hand, the immobilization often causes a reduction of catalytic activity. Immobilized enzyme systems always differ from the soluble counterparts by the \( K_m \) value or the optimal pH condition.

A further advantage of immobilization is the possibility to prepare multienzyme systems, where two or more enzymes immobilized on the same carrier. Immobilized multienzyme systems are suitable to catalyze sequential sets of reactions.

The application of immobilized enzymes in flow systems is a very convenient way for rapid and automated enzymatic determinations. The most common configurations in such flow systems are packed bed reactors or open-tube wall reactors.

In packed bed reactors especially covalent enzyme binding on controlled pore glass (CPG) or polymeric carrier is used. In open-tube reactors the enzymes are bounded to the inner surface of tubes. The sample-handling technique used in packed bed reactors and open-tube wall reactors is the flow injection analysis (FIA). FIA means short analysis times, and ease of automation. FIA is based on the injection of the liquid sample into a nonsegmented continuous buffer stream. \tag{41}

The injected sample forms a zone in the stream, which is then flowing into the enzyme reactor. There the enzyme reaction takes place and the resultant change in a physical-chemical parameter (e.g. absorption, temperature, pH) is registered by the detector. Figure 9 shows a practicable arrangement of the flow system for enzymatic determinations in a simplified representation.

The detector signal during the passage of the sample (substrate zone) has the form of a peak. The analytical information is given by the peak height, the peak area or

**Figure 9** Simplest arrangement of enzymatic flow system. P: pump; V: valve; ER: enzyme reactor; D: detector.
the width of the peak, which is analogous to the exploration in chromatographic measurements. The enzymatic flow systems are calibrated with standard solutions before their application. The operating conditions, as pH, buffer system or buffer flow stream have to be optimized. In FIA systems kinetic controlled reactions take place.

The arrangements of enzymatic flow injection systems vary with the analytical problem to be solved. A review of FIA techniques is given in Ružička and Hansen; the authors introduced this method in the analytical chemistry. Multiline manifolds, combination of several enzyme reactors, enzyme reactors with multienzyme immobilization are described, also.

Enzymatic flow systems are suitable to determine substrates, coenzymes, inhibitors or enzyme activities, and for application such as on-line monitoring, control of biotechnological processes or medicine.

In the following some interesting examples of application of immobilized enzymes in flow systems are represented. The use of immobilized enzymes to construct biosensors, which can also incorporate in flow systems, is explained in section 7.

A FIA system for measuring of acetate, ethanol, glucose, L-lactate and pyruvate is developed by Schürgel and Rhee, and described by Equations (42–46). Alcohol oxidase (AOD, E.C. 1.1.3.13, 9073-63-6), GOD (E.C. 1.1.3.4, 9001-37-0), LDH (E.C. 1.1.1.27, 9001-60-9), lactate monooxygenase (LMO, E.C. 1.13.12.4, 9028-72-2) and sarcosine oxidase (SOD, E.C. 1.5.5.1, 9029-22-5) were immobilized on VA-Epoxy-Biosynth E3 carrier. In that publication the influence of metabolites on enzyme based FIA is investigated. Three different detection methods are used. The oxygen consumption (Equations 42–44) is evaluated with an oxygen electrode, the peroxide production (Equation 46) is detected with the redox indicator 2,2'-azino-di(3-ethylbenzthiazoli-sulfonic acid)-6 (ABTS), and the NADH reduction (Equation 45) is evaluated spectrophotometrically.

\[
\text{ethanol} + \text{O}_2 \rightarrow \text{acetaldehyde} + \text{H}_2\text{O}_2 \quad (42)
\]

\[
\text{glucose} + \text{O}_2 \rightarrow \text{gluconic acid} + \text{H}_2\text{O}_2 \quad (43)
\]

\[
\text{L-lactate} + \text{O}_2 \rightarrow \text{acetate} + \text{CO}_2 + \text{H}_2\text{O} \quad (44)
\]

\[
\text{pyruvate} + \text{NADH} + \text{H}^+ \rightarrow \text{L-lactate} + \text{NAD}^+ \quad (45)
\]

\[
\text{sarcosine} + \text{H}_2\text{O} + \text{O}_2 \rightarrow \text{glycine} + \text{formaldehyde} + \text{H}_2\text{O}_2 \quad (46)
\]

Since acetate is a competitive inhibitor of the reaction with SOD, the reduction of the reaction rate (Equation 46) is proportional to the concentration of acetate.

A recent trend in analytical chemistry is the miniaturization. As an example capillary flow injection (CFI) is combined with an immobilized enzyme reactor (open tubular capillary reactor). The glucose determination in juice and soft drinks has been described. Chloramine is used as bleaching and disinfecting agent or antiseptic. Its determination, based on an inhibition reaction, is discussed. Chloramine is an inhibitor of peroxidase. The flow injection peroxidase reactor is made out of a steel tube in which the enzyme immobilize (polymer carrier) is filled. A detection limit for chloramide of 26 µmol L\(^{-1}\) was obtained.

An automated system for multichannel FIA, in which up to six different analytes can be determined sequentially, is described. The enzyme reactors are configured in parallel and only one fluorescence detector is necessary for the sequentially implemented determinations. Furthermore the FIA stopped flow method is used to control the analyte conversion and to optimize multistep enzymatic assays.

FIA technique in combination with immobilized enzymes is a powerful tool for on-line monitoring of cultivation processes. The concentrations of penicillin and glucose have been measured online during penicillin production by the filamentous fungus Penicillium chrysogenum. In this publication a development of FIA, called sequential injection analysis (SIA), has been employed. SIA allows the determination of more than one component in the same manifold.

An example of the use of coimmobilized enzymes is given. G6PDH and diaphorase (E.C. 1.6.99.1, 9001-68-7) are employed to enhance the sensitivity of NAD(P) coenzymes as on-line amplifiers on substrate recycling (see section 5.1) in a chemiluminometric flow injection system.

The combination of immobilized enzymes in flow systems with calorimetric detection is used in the enzyme thermistor device (ET). The immobilized enzymes arranged in columns and the temperature is generally measured at the top of the column with a thermistor. As a result of the enzyme catalyzed reaction, a temperature peak can be detected. The height of the peak is proportional to the enthalpy change, corresponding to a definite substrate concentration. Normally, the ET device is calibrated with known concentrations of an analyte. With such an arrangement many substances can be determined.

Another recently developed flow instrument is bypass trapped flow analysis system (ByT-FAS). The ByT-FAS is applied to evaluate enzyme kinetic parameters by use of coupled enzyme assay (HK and G6PDH) and fluorescence detection.
Flow injection analytical biosystems based on open-tube and packed bed enzyme reactors have been compared. Three different enzymes: urease (E.C. 3.5.1.5, 9002-23-5); creatine iminohydrolase (E.C. 3.5.4.21, 37289-15-9); and creatine amidohydrolase (E.C. 3.5.3.3, 37340-58-2) were covalently immobilized on CPG beads as the filling for the packed-bed reactor and immobilized covalently on the inner wall of nylon tube reactors. The authors notice, that packed bed reactors would be ideal for applications requiring a high sensitivity or measurements of low concentration, whereas open-tubular reactors will be best for applications involving samples with a high concentration or requiring saving in the reagents used or shorter analysis times.

7 IMMOBILIZED ENZYMES IN BIOSENSOR DEVELOPMENT

One of the first applications of immobilized enzymes in analytical chemistry was the construction of an enzyme electrode for glucose determination. An oxygen electrode, Clark type, was combined with a thin layer of GOD entrapped in a polyacrylamide gel. Such enzyme electrode form a major category of so called biosensors.

Literature lacks a standardized definition of the term biosensor. Generally, the biosensor is a measuring device that contains a biological element. The biological or biorecognition element may be an enzyme, antibody or microorganism system. Besides the biological element, or in sensor development called receptor, the biosensor consists of a transducer, that interprets the interaction of the analyte with the receptor as an electrical signal, related to the concentration (or activity) of a chemical or biochemical analyte (see Figure 10). For instance an enzymatic catalyzed reaction may produce ions, electrons, heat, color or changes in mass, used in the transducer to provide an electrical output. The receptor as a biorecognition element imparts the required high analyte selectivity to the transducer.

Usually, the enzyme is immobilized directly at the surface of the transducer or entrapped in gel or rather in membranes, fixed immediately at the transducer. Pertinent information about the immobilization of biological components for biosensor application is published by Eggins. The optimization of the enzyme immobilization is one of the critical issues of biosensor development. Problems with long term stability of enzyme layers and long response times of biosensors have to be solved. Frequently, membranes used to separate the enzyme layer and the medium. Because of this, additional barriers, not only the enzyme kinetics but also diffusion effects, have to be taken into account. Furthermore, the biosensor signal is also influenced by temperature, inhibitors and pH value. In many practical applications, the highest efficiency can be achieved in combination with FIA systems.

Advantages of biosensors are the detection of biological and chemical substances without the need for complex sample processing, simple method for use outside of a laboratory and the great potential of miniaturization by combination with the microsystem technique. Biosensors excel by a high selectivity and sensitivity.

In the following some examples of biosensors from the four principal transducer classes

- amperometric
- potentiometric
- optic
- calorimetric

are represented.

An extensive representation of the different transducer principles is given in Göpel, Hesse and Zemel.

Amperometric biosensors monitor currents in the transducer generated when electrons are exchanged between a biological system and an electrode. Many blood glucose sensors are based on this principle. A prominent representative is the glucose analyzer Yellow Springs Instrument for the measurement of glucose (according to Equations 27 and 28, section 5.1) in whole blood. The applicability of this instrument has been expanded for the determination of for instance lactate, alcohol, uric acid and ascorbic acid. A list of enzyme electrode-based autoanalyzers and their application are given in Kress-Rogers.

Potentiometric devices measure the accumulation of charge density at the surface of an electrode, especially pH-sensitive electrodes are used. Any enzyme reaction, affecting the acid–base equilibrium can be applied. Potentiometric enzyme sensors based on ion-sensitive field effect transistors (ISFETs) are also called enzyme field effect transistors (ENFETs). ENFETs are chiefly used for the determination of glucose, urea and penicillin. Moreover potentiometric enzyme sensors are employed for the determination of inhibitors. Copper(II) in water is determined in the ppm range without preconcentration, based on the urease inhibition and by means of an ISFET. The urease is immobilized onto the pH-sensitive gate area of an ISFET. Authors used a photopolymer system

![Figure 10 General principle for a biosensor.](image-url)
with urease to prepare photolithographically patterned enzyme membranes.

An example for the optical transducer principle are fiber-optic biosensors. A dual-enzyme fiber-optic biosensor for pyruvate determination is described. This biosensor is based on the fluorometric detection of NADH and immobilized enzyme recycling system (see section 5.1) to amplify the sensitivity. The enzyme layer composed of lactate oxidase (LOD) and LDH is prepared at the tip of a sensing optrode. The described operating principle is illustrated in Figure 11.

The temperature changes during enzymatic reactions, as a consequence of heat exchange, are detected in biosensors with thermal transducer principle. A comprehensive representation of such transducer principle is given in Scheper.

An integrated thermal biosensor array for multianalyte determination is described. A single microchannel is partitioned into three distinct detection regions. Each of the regions is filled with one immobilized enzyme and contains a pair of thermistors for differential measurement of temperature changes, released by the enzymatic reaction. The pair of thin-film thermistors are placed upstream and downstream of each enzyme matrix. An enzyme-free region is arranged between two adjacent enzyme regions to damp thermal carryover. The authors demonstrate this sensor array with determinations of glucose, urea and penicillin. They applied GOD, urease and β-lactamase (E.C. 3.5.2.6, 9001-74-5), immobilized on N-hydroxysuccinimide (NHS)-activated agarose beads.

Xie et al. applied a combination of two transducer principles: a hybrid biosensor for simultaneous electrochemical and thermometric detection of catechol. This biosensor is based on the tyrosinase (1.14.18.1, 9002-10-2) catalyzed reaction Equation (47):

\[
\text{catechol} + \frac{1}{2} \text{O}_2 \xrightarrow{\text{tyrosinase}} 1,2 \text{benzochinon} + \text{H}_2\text{O}
\]

with the electrochemical regeneration of catechol by Equation (48):

\[
1,2 \text{benzochinon} + 2\text{H}^+ + 2\text{e}^- \xrightarrow{\text{response}: \Delta q} \text{catechol}
\]

The hybrid biosensor concept uses the individual advantage of thermal and electrochemical detection principle.

In kinetic methods or reaction-rate methods of analysis, the rate of a given reaction is measured and related to the concentration of the sought-for species. The instrumentation in kinetics is primarily designed to monitor the evolution of the analytical signal with time. Unlike in the traditional equilibrium-based approaches, where the signal is measured after the reaction has reached completion, in kinetic methods the signal is usually measured in the first few percent of the total reaction time. Therefore, the advantages and limitations of kinetic methods should be considered in their relations with equilibrium methods. Kinetic methods are faster than equilibrium-based methods since the user does not have to wait for a reaction to go to completion. They are relative methods that depend on changes in concentration and not on its absolute value and they could be more selective than equilibrium methods since the difference between reaction constants could be used to discriminate against an interfering species. The limitations of kinetic methods are a lower precision and a strong dependence on experimental conditions. The main factors that cause these limitations are the measured signal, which is small in comparison with that from an equilibrium reaction, and the dependence of rate constants on temperature, pH, ionic strength, etc. Therefore, the measurement systems used in kinetic methods should be sensitive and the experimental conditions should be kept strictly constant. The best results in kinetic methods are obtained with instrumental systems having a high degree of automation.

The main operations that should be carried out by the instrumentation in kinetic determinations are the mixing of the reactants, measurement of the detector signal in time and processing of data to obtain the reaction rate and concentration. The mixing of the reactants should be done in a time shorter than the reaction half-life and it is critical for fast reactions where required mixing times are of the order of milliseconds. In these cases the mixing is accomplished by mechanical systems that rapidly drive the reactants through a mixing chamber into an observation chamber. For slower reaction the best mixing procedures are based on automated flow analyzers that have different manifolds configurations adapted both to sample processing and to reactant mixing. After mixing, the reaction could be monitored in time either by stopping the flow and recording the signal or by passing the reacting plug several times through the detector and reading the signal after each pass. The measurement of the detector signal, after the reagents are mixed, could be done with a large variety of detectors, but the most commonly used detection systems are photometric and electrochemical. Photometric detection provides a short response time, specificity and the possibility of collecting full spectra very rapidly if photodetector arrays are used. Electrochemical detectors are simple and relatively inexpensive. The concentration of the analyte is determined from the slope of the detector signal. In many routine procedures the slope is determined by measuring the signal at one or two fixed points in time or by determining the time required by the signal to reach a predetermined level. These procedures have the advantage that they are rapid and need no supplementary instrumentation for data processing. Another approach in kinetic data processing, based on computer software, computes a curve that fits the mathematical expression of the fitting curve.

1 INTRODUCTION

Kinetic methods of analysis are based on the determination of the rate of a given reaction in which the sought-for species is involved. The reaction rate is then correlated with the concentration. Consequently, the instrumentation in kinetics is primarily designed to monitor the evolution of the analytical signal with the time.

The use of kinetic methods is always considered in their relation with the well-established equilibrium methods because many analytical determinations could be
performed by either of the two types of method.\(^{1–3}\) The main advantages of kinetic methods concern speed, relativity and selectivity. Kinetic methods have a potential speed advantage over equilibrium-based methods since the user does not have to wait for a reaction to go to completion. They are inherently relative methods and do not depend on absolute concentration but on changes in concentration. Kinetic methods could be more selective than equilibrium methods. The difference between reaction constants could be used to discriminate against an interfering species or to perform multicomponent determinations. Kinetic methods permit the determination of catalyst concentration, which cannot be readily determined by equilibrium-based methods.

The limits of kinetic methods should be carefully considered when using or designing instrumentation for kinetic determinations. The change in analytical signal that is measured is small in comparison with that from an equilibrium reaction. The consequence is a lower precision and the need to have very sensitive measurement systems. The rate of a reaction is dependent, via the rate constants, on experimental conditions: temperature, pH, ionic strength, etc. Therefore, the experimental conditions should be kept strictly constant. This is why automated systems give the best results in kinetic determinations and many of the modern instruments involved in rate methods have a high degree of automation.

The main operations in a kinetic method of analysis are the mixing of the reactants, measurement of the detector signal in time and processing of data to obtain the reaction rate and concentration. For each of these stages a unit in a block diagram of the instrument could be identified. A general block diagram of a complete instrumentation system for reaction rate methods is given in Figure 1.

The mixing of the reactants is a key operation in kinetic methods. In most kinetic methods the use of the initial rate of reaction is recommended, which means that the rate measurement should be made just after the reaction was initiated. Therefore, the time taken for mixing should be shorter than the reaction half-life. In the case of fast reactions, the required mixing times are of the order of milliseconds. For these reactions the mixing is accomplished by mechanical systems that drive the reactants through a mixing chamber, rapidly enough to have turbulent flow and rapid and thorough mixing. The observation is made in a region very close to the point where the reactants were completely mixed.

For slower reactions, the mixing could be done manually or with automated systems. Flow analyzers are the most widespread instrumental solution for the automation of kinetic methods. Once the reactants have been mixed in the analyzer manifold, the reaction could be monitored in time either by stopping the flow and recording the signal or by passing the reacting plug several times through the detector and reading the signal after each pass.

The monitoring of the analytical signal after the reagents are mixed could be done with a large variety of detectors that should be selected considering the type of reaction and its rate. The detectors should be sensitive enough to detect small changes in the monitored parameter and their response time must be much shorter than the reaction half-life. The most commonly used detection systems are electrochemical and photometric. Electrochemical detectors are simple and relatively inexpensive. However, most detection methods used in kinetic determinations are photometric. Photometric detection is attractive because of the very short response time of modern photodetectors and the specificity of the spectrophotometric measurements. A wealth of information could be obtained if photodetector arrays are used to collect full spectra during the initial stage of the reaction.

In the final step of analysis the concentration should be determined from the slope of the detector signal. The slope could be determined explicitly if the signal was recorded in time, as a tangent to the kinetic curve. For routine applications, however, it is more convenient to simplify the slope determination by measuring the signal at one or two fixed points in time or to determine the
time required for the signal to reach a predetermined level (fixed-time and variable-time methods). These procedures predominate in routine analysis and even in many publications since they are rapid and need little or no supplementary instrumentation for data processing.

A more modern approach to kinetic data processing is based on computer software. Instead of the direct determination of the slope and concentration, a curve that fits the experimental data is computed. All the required data are then extracted from the mathematical expression for the fitting curve. The advantages of a curve-fitting procedure are multiple, e.g. a reduced effect of the noise and the possibility of extracting more information about rate constants and about the values of the equilibrium response by using a predictive manner approach. In the same category of advantages are the applications of error compensation methods and multicomponent analysis.

2 SAMPLE AND REAGENT PREPARATION, REACTANT PROPORTIONING AND MIXING

The sample and reagent preparation and the proportioning and mixing of the reactants are the most important, and sometimes the weakest, links in the chain of the instrumentation system. The development and automation of kinetic instrumentation in the last three decades focused on these parts of the diagram in Figure 1.

The sample preparation system must provide treatment operations that include dissolution in the case of solid samples, pH adjustment, extraction and removal of interfering components. The reagent preparation, in addition to simply preparing the reagent, is often used to dispense and mix the reagent in form of a single composite reagent.

The first approach to sample and reagent handling and mixing was that of manually pipeting sample and reagents into a reaction vessel that served both as mixing chamber and observation cell (the pour-and-shake technique). For a slow reaction the reactants could be mixed externally and then transferred to the observation cell. Most spectrophotometers have a pumping system that could aspirate the sample and reagent mixture and transfer it in a cuvette.

Today most kinetic instrumentation is automated to various degrees and adapted to fast or slow reactions. The sample and reagent preparation is often accomplished within the instrumental system, on-line, especially in flow analyzers. There are two main categories of techniques and analyzers in approaching the reactants preparation and mixing: stopped-flow analyzers for fast reaction and flow analyzers for slower reactions. A different novel approach that could be applied for fast reactions is based on continuous reagent addition.

2.1 Stopped-flow Analyzers

The stopped-flow technique consists of rapidly mixing the reactants by forcing the solutions through a mixing chamber and into an observation cell. The flow of solution is abruptly stopped, creating a back-pressure which completes the mixing, and the rate measurement is rapidly made. The more sudden the stopping, the faster the reaction can be observed. The stopped-flow technique is suitable for fast reactions with half-lives of a few milliseconds to few seconds.

The term “stopped-flow” is also used in continuous-flow techniques. It indicates a similar principle of operation that consists in halting the flow, recording the detector signal and measuring the slope of the obtained kinetic curve. However, the operating conditions are different from that of the normal stopped-flow technique. The relatively low flow rate of the solutions and the fact that sample and reagents are not mixed under high pressure and turbulent flow conditions does not allow the measurement of fast reactions. Therefore, the term “stopped-flow mode” will be used for this type of operation in continuous-flow techniques.

The basic components of a stopped-flow system are the driving syringes, mixing chamber, observation cell and the stopping syringe. The detection system used in connection with the observation cell should measure a certain property of the mixed solutions. The detection systems are spectrophotometric, fluorescence or both. A few other types of detection systems for analytical application have also been devised. However, many detection systems that are not photometric were intended rather for kinetic studies of reactions.

An example of an automatic stopped-flow system is shown schematically in Figure 2. The driving syringes could be actuated by a motor and cam device or by a pneumatic system. Upon activation of the system, the sample and the reagents are drawn into the syringes. Then, after the three-way stopcock has been set in a proper position by the stopcock motor, the actuating system pushes the pistons and the solutions are rapidly driven out of the syringes. The solutions are forced into the mixing chamber and on to the observation cell. The reactants mixture flows through the observation cell until the flow is abruptly stopped by the stopping syringe. From the instant the syringe hits the mechanical stop the reaction rate curve could be recorded or the data fed to a computer. A family of stopped-flow kinetic curves obtained for the determination of lysozyme with fluorimetric detection is given in Figure 3.
The efficiency of the stopped-flow system is dependent upon the flow velocity, mixer design and the distance between the mixer and the observation cell. It implies that the flow of solution must be turbulent. At a Reynolds number of about 2000 for short tubes with streamline entry, turbulent conditions, and consequently good mixing, are achieved at flow rates usually higher than 1 m s\(^{-1}\). However, a very high flow rate could lead to cavitation effects produced by the unequal hydrostatic pressure of the streaming fluid in different portions of the tube. This will affect the precision of the reaction rate determinations, especially for spectrophotometric detection. Therefore, a compromise is made so that the flow rate is high enough to produce a turbulent flow and low enough to prevent cavitation.\(^9\)

In obtaining a fast flow rate, the quality of the driving and stopping syringes is a key factor. The syringes are usually made from frosted-glass barrels and ceramic-tipped plungers. The problems that may arise in syringe functioning are those resulting from the difference in thermal expansion of the barrel material and plunger and those related to sealing and lubrication. Both of these problems could lead to breakage or "blow-by" during rapid acceleration that is required to obtain fast flow rates and to reduce the instrument dead time. Part of these could be avoided by using smooth-bore glass barrels and Teflon\textsuperscript{®} plunger tips.\(^10\)

Most stopped-flow instruments are provided with thermostating systems for the driving syringes and reagents reservoirs to insure the constant temperature required by reaction rate measurements. Uncontrolled temperature changes may have undesirable effects on the rate of studied reaction and on the precision of analytical measurements. Temperature changes may result from the thermal gradient between different parts of the system or by heating during the compression and mixing of the reagents.\(^11\)

The mixing efficiency, in turn, is dependent of mixing design. High mixing efficiencies are obtained using tangentially offset jets that promote a rotary motion of the fluid.\(^12,13\) An increased number of jets and a higher jet velocity also contribute to higher efficiency. For a given mixer it means more jets with a smaller jet bore diameter. To avoid excess pressure drop in the mixer, the total area of the jet bores should be equal to that of the section of the observation cell. More than one mixer could be used, in cascade, both to increase the efficiency and to mix more than two different solutions.

A measure of the mixing efficiency is the dead time. It is defined as the time interval from the initial contact of the two solutions in the mixing chamber to the observation measurement point in the cell. If \(d_m\) is the distance, in meters, from the mixing chamber outlet to an observation point where the solutions are thoroughly mixed and \(v\) is the flow velocity in meters per second, the dead time is
given by Equation (1):

\[ t_m = \frac{d_m}{v} \]  

(1)

It is desirable to provide a dead time as small as possible. This could be accomplished either by improving the mixing design and thus decreasing the distance \( d_m \) from the mixer outlet to the point where the solutions are mixed or by increasing the flow velocity, \( v \). Typically the dead time is in the millisecond range.\(^{14,15}\)

In most instruments the mixer and the observation cell are part of the same unit. A schematic diagram of the driving syringe block and a vertical section of mixing and observation cell with spectrophotometric detection are given in Figure 4(a) and (b).\(^9\) The syringe block could be considered as an aliquoting system that delivers solutions to the mixer. The sample and the composite reagent are mixed in a two-stage mixing chamber, introduced into the observation cell and pushed further through the block outlet to the stopping syringe. To minimize the dead time, the mixing chamber is located as close as possible to the observation cell.

The mixers and the observation cell are built from stainless steel, quartz,\(^{16,17}\) fused silica\(^{18}\) or polymers (Kel-F\(^{18}\)).\(^{19}\) In some of the commercial stopped-flow units the mixing chamber and observation cell are designed as a single block that could be easily fitted and removed from the cuvette compartment.
of the existing spectrophotometers.\textsuperscript{18} The design of stopped-flow syringe block implies that the volumes of solution delivered or their ratio are fixed. Therefore, a composite reagent is often used. To facilitate the adaptation of the method to more complex chemical reactions, mixing devices that allow predilution of the reactants have been devised.\textsuperscript{20,21}

2.1.1 Pulse-accelerated Flow

Pulse-accelerated flow (PAF) is a procedure that allows the measurement of single-step reactions with half-lives from 0.5 ms to 4 µs.\textsuperscript{22} The instrumentation is basically that of a stopped flow with motor-driven syringes (Figure 5). Instead of completely stopping the flow, a deceleration is applied and the flow velocity is reduced from 21 to 2 m s\textsuperscript{-1}. Reactions are observed as mixing takes place. Chemical rate processes are resolved from physical mixing rate process by variation of flow velocities under turbulent flow conditions. An integrating system of observation or position-resolved observation could be used. For position-resolved observation see section 3.2.

![Figure 5](image-url) Schematic diagram of PAF spectrometer with position-resolved observation. [Reprinted with permission from M.R. McDonald, T.X. Wang, M. Gazda, W.M. Scheper, S.W. Evetts, D.W. Margerum, Anal. Chem., 69(17), 3513–3520. Copyright 1997 American Chemical Society.]
2.2 Flow Analyzers

Flow analyzers are the most widespread type of automated instruments that could be adapted both to equilibrium methods and kinetic methods. Flow analyzers are based on the sample treatment as it is transported by a flowing stream through a manifold made of interconnected tubing. There are two main techniques in accomplishing this method. One is based on the segmentation of the reagents flow with air bubbles [air-segmented continuous-flow analysis (ASCFA)], the sample being introduced into the flow by aspiration by the same pumping unit as for the reagents.(23) In the second technique, the reagent flow is continuous, nonsegmented, and the sample is injected into a carrier flow at a certain point of the manifold [flow-injection analysis (FIA)].(24,25) Combinations between these two techniques are also known.(26)

The main components of a flow analyzer are a propelling and aspiration system for reagents and sample, tubing manifold and a detector unit. For the air-segmented technique a debubbling device is included prior to the detection or an electronic bubble gate is used, so that the detection is done only when the solution is in the detector unit.(27) For FIA a sample injection valve is added, usually on the carrier stream.

The most frequently used device for obtaining a constant reagent flow is the peristaltic pump, although a number of other devices have been used: gas-pressure propulsion, syringes, linear and sinusoidal pumps.(28,29) Usually a six-channel peristaltic pump is sufficient for a single-channel analyzer.

The manifold consists of a coiled tube that insures radial mixing of sample and reagent. If more reagents have to be used in succession more streams are confounded by adding more coils. Coiled tubes provide better mixing than straight tubing.(30) Tubes are made of glass, fused silica, plastics with inner diameters from about 1 mm down to 100 µm for capillary flow injection.(31–35) In the manifold structure could be included miniaturized packed reactors to process the sample further. The packed reactors could contain reagents,(36) immobilized enzymes,(37,38) ion exchangers(39) or polymer-based C18 materials.(40) Finally, the stream of reaction products flows through a detection system adapted to the small volumes of solutions.

Using the above-mentioned basic modules of the instrumentation a number of techniques are applied for reaction rate measurements.

2.2.1 Flow Analyzers in Stopped-flow Mode

The instrumentation includes the basic flow analysis set-up and a stop-and-go sequence provided by the computer or the circuitry that controls the instrument. The stream is started and when the mixture of sample and reagent reaches the detector the flow is stopped and the signal changes in time is monitored.(41) It could be accomplished as either an FIA(42) or an ASCFA technique.(43) An example of a stopped-flow injection instrumental set-up and the resulting kinetic curve is given in Figure 6(a) and (b). Here, the reactor is the called the sum of tubing, coils and T-mixers of the manifold where the reaction and/or subsequent reactions take place. By turning the sample valve a given amount of sample is injected into the carrier stream. The first rising portion of the signal indicates the moment the reacting plug has reached the detector. As the stream flows, the signal begins to decrease as the front of the reacting plug passes by. Stopping the flow after a time  (delay time) will result in an increase in the signal as reaction proceeds in the observation cell. The slope of the signal during the stop interval (reaction rate) is proportional to the analyte concentration. An example of a kinetic curve family obtained by stopped-flow injection is given in Figure 7 for glucose standards in glucose determination by the Trinder enzymatic reaction.(44)

2.2.2 Sequential Injection Stopped Flow

The techniques of sequential injection (SI) is based on the dispersion and mutual penetration of the sample and
reagents zones as they are stacked in a holding coil, adjacent to each other. The sampling valve has multiple ports so that sample, reagents and the carrier could be alternatively aspirated and propelled through the reactor to the detector (SI).\(^{45}\) A diagram of the instrumental set-up and its functioning in the stopped-flow mode is given in Figure 8(a–c).

A high-precision piston pump or a peristaltic pump could be used to control the forward and reverse movement of the liquid flow. The first step is the aspiration of precisely measured volumes of carrier, sample and reagent into the holding coil (Figure 8a). Then the pump movement is reversed and the stack is propelled through the selector valve and reactor (Figure 8b) to the detector. The reversal of the flow creates a composite zone in which sample and reagent zones mutually penetrate. When the stack reaches the detector, the pump stops the flow (Figure 8c) and from this moment the kinetic curve could be recorded or the reaction rate could be determined (Figure 8e).

SI requires a simpler mechanics than flow injection. It uses a single pump, a single valve and a single channel. By designing appropriate software the SI technique becomes very versatile in configuring the analytical systems. Injection volumes, reaction times and zone dispersion could be changed via the computer by varying stroke volumes, flow rates and stopped-flow time.

In a recent kinetic application, SI was used for mechanistic studies and kinetic determination of bromazepam.\(^{46}\)
2.2.3 Flow Recycle Analyzers

The kinetic information is obtained by passing the reacting plug several times through the detector until it is completely dispersed into the carrier. After each pass the signal shows a peak. The number of peaks obtained per sample is a function of its volume, flow rate and the reactor length. The envelope of the maximum (or minimum) of these peaks defines a kinetic curve that allows the application of conventional kinetic methods of determination and calculations of the partial reaction orders and rate constants. The technique could be implemented both with unsegmented flow or air-segmented flow systems. The air-segmented flow system gives lower dispersion and shorter peaks than nonsegmented flow procedure.

The instrumentation involves, in addition to the basic modules of a regular flow analyzer, a switching valve and a unidirectional peristaltic pump. A diagram of a flow recycle system, unsegmented type, and a typical kinetic curve are given in Figure 9(a–c). It works as an open–closed system. The sample is injected and carried until it passes through the detection system. Then the valve is switched and the reacting plug is transported in a closed loop by the unidirectional peristaltic pump. Instrumental versions of this technique in which the recycling is done using only the main peristaltic pump and a pair of switching valves are also known.

2.2.4 Flow Reversal Analyzers

The kinetic response of this type of analyzers is obtained by passing the reacting plug several times through the detector, but alternately in opposite directions. The manifold for an air-segmented flow reversal analyzer and the corresponding response curve are given in Figure 10(a–c). The reversal of the flow direction, via the selecting valve, is activated when the detector signal falls...
to zero. Compared with the normal flow, peaks obtained by flow reversal are narrower and more Gaussian, with lower dispersion. This is mainly because of the way the flow is circulated and the fact that the sample does not travel through the whole flow injection system. This type of analyzer is particularly well suited for very slow reactions. Flow reversal analyzers are used both in unsegmented flow and in air-segmented flow modes.

### 2.3 Continuous Reagent Addition Method

In this method, the reagent with which the analyte reacts is added continuously, at a constant rate, to the solution of the analyte and other reaction ingredients. The instrumentation is fairly simple and consists of a reaction vessel with an adequate stirring and an automatic burette. Using an immersion probe for photometric detection allows for smaller reaction vessels and lower sample consumption (Figure 11a). The analyzers of this type are especially suited to fast reactions and offer a major alternative to the stopped-flow analyzers. The analyte concentration during this addition varies because of both reaction and dilution. The overall reaction is of second order.

A typical kinetic curve is given in Figure 11(b). There are two portions on this curve, which are of analytical interest. The first is the initial concave segment that conforms to Equation (2):

$$\Delta S = 0.5\varepsilon_p u V_0^{-1}k[R]_0[A]_0 t^2$$  \hspace{1cm} (2)

where $\Delta S$ is the change in analytical signal, $\varepsilon_p$ the molar absorptivity of the product, $V_0$ the initial sample volume, $k$ the second-order rate constant, $[R]_0$ the reagent concentration in the automatic burette, $[A]_0$ the initial concentration of the analyte and $t$ time. Equation (2) shows that the analytical signal is directly proportional to $t^2$. The analyte concentration could be determined from this segment of the kinetic curve using the initial reaction method.

The second segment of interest on the kinetic curve is the linear intermediate portion that follows Equation (3):

$$\frac{dS}{dt} \approx 0.55\varepsilon_p[A]_0 \left( \frac{k[R]_0}{V_0} \right)^{1/2}$$  \hspace{1cm} (3)

where the subscript $m$ signifies the maximum reaction.

In comparing the two possible approaches to the kinetic curve, the maximum reaction method yields a smaller error, for instrumental reasons, while the initial reaction method is less affected by side reactions since the measurements are made at the beginning of the reaction. However, the maximum reaction method is preferred since it is less sensitive to between-run variations arising from the rate constants and the measurements are made on a much larger linear portion.

![Figure 11](image-url)

Figure 11 Schematic diagram of the instrumentation and kinetic curve for continuous reagent addition method. (a) Instrumentation used with photometric detection; (b) typical kinetic curve; (c) recording obtained for a chemical system involving an undesirable reaction. [Reproduced by permission of The Royal Society of Chemistry from M. Silva, *Analyst*, 118(6), 681–688 (1993).]

The continuous reagent addition method was applied for single-element determinations and on pharmaceuticals, biological and clinical samples.
2.3.1 Continuous-flow Stirred Tank Reactor

The principle of the continuous flow of reagent could be used to apply the analyte pulse perturbation (APP) technique on oscillating chemical reactions and to use these reactions for analytical purposes. The most convenient instrumental set-up for APP is the continuous-flow stirred tank reactor (CSTR). The continuous-flow component of a CSTR is provided by a peristaltic pump, that pumps the required reagents into a thermostatted receiver. The reagent mixture is well stirred and its volume is kept constant by an overflow channel provided by the same peristaltic pump. The reaction is monitored in the receiver, usually by photometric or electrochemical detection. The CSTR could be considered a homogeneous system, where mass and energy are continuously exchanged with the surrounding environment and the reactions occur in far from thermodynamic equilibrium conditions.\(^{(69)}\)

The APP technique is based on the change in amplitude or period of an oscillating reaction produced by a microvolume of an analyte solution added to the reactant mixture.\(^{(70)}\) The reactions most frequently used are the Belousov–Zhabotinskii reaction, based on the oxidation of malonic acid by bromate ions in concentrated sulfuric acid, and copper oscillators based on the oxidation of KSCN by \(\text{H}_2\text{O}_2\) in a strongly alkaline medium, which is catalyzed by traces of copper. The APP technique has been used on copper oscillators for the determination of vitamin B\(_6\),\(^{(71)}\) gallic acid and paracetamol,\(^{(72,73)}\) resorcinol\(^{(74)}\) and glutathione.\(^{(75)}\)

### 3 REACTION MONITORING SYSTEMS

Any suitable means of monitoring the concentration of a chemical species can be used in reaction rate methods. Most frequently, spectrochemical and electrochemical methods are used for monitoring but a smaller number of methods based on other chemical or physical parameters have been described. In selecting an appropriate transducer, the nature of the monitored species, the type of reaction and its rate must be considered. The transducer should be sufficiently sensitive to provide detection of very small changes in measured reaction parameter and must have a response time which is short relative to the reaction half-time to prevent distortion of the resultant rate curve.

The kinetic information could be obtained using single- or multichannel detection systems. Single-channel detection systems produce a single response, proportional to the reactant or product concentration versus time. Multichannel or multidimensional detection systems provide simultaneous (or quasi-simultaneous) responses from the same chemical reaction. The multidimensional detection could be achieved by using a single type of detector or by combining more types of detectors.\(^{(2)}\)

#### 3.1 Single-channel Detection

##### 3.1.1 Electrochemical Monitoring

Electrochemical-based devices are attractive mainly because of instrumental simplicity and relatively low cost. Most of the instruments are based on potentiometric and amperometric detection but detectors based on conductometry, chronamperometry and voltammetry are also used. Since most kinetic determinations are accomplished by means of flow analyzers, the detectors for this type of instrumentation will be considered.

**Potentiometric detection** is based on monitoring the potential of an indicating electrode. The main indicating electrodes in kinetic determinations are metallic electrodes, carbon-based electrodes, ion-selective electrodes (ISEs) and enzyme electrodes. The reference electrode is usually an Ag/AgCl electrode.

Copper-wire electrodes were used for the detection of amines in a flow-injection system.\(^{(76)}\) A flow cell containing eight Ag electrodes in the carrier channel and one Ag electrode in the reference channel was used for determination of Ag\(^+\) and iodide ions.\(^{(77)}\) The potential of a silver metal electrode was measured to detect the metal cyanide complex formation. Ag, Hg(II), Fe(III), Cu(II), Zn, Co(II) or Ni(II) were determined in a flow-injection analyzer with 0.29 mM cyanide solution as carrier.\(^{(78)}\) Aluminum ions were detected by an Al-wire indicator electrode with an Ag-wire reference electrode in a carrier solution of 1 mM fluoride in 0.05 M acetate buffer of pH 5.\(^{(79)}\)

ISEs and biosensors are known for many analytical species. The electrode response time varies according to both the type of electrode and the conditions under which it is used. For detection in flow analyzers where the electrode volume should be small and its response time short, the ionophore is incorporated in a polymer and applied as a thin layer on a metallic wire (ion-selective coated-wire electrodes).\(^{(80–82)}\)

A solid-state Br\(^-\) electrode in conjunction with a double-junction Ag/AgCl reference electrode was used for potentiometric monitoring of Br in the kinetic determination of pyridoxine.\(^{(83)}\) A Br\(^-\)-selective electrode is used for monitoring the potential oscillations in the Belousov–Zhabotinskii reaction in kinetic determination of hexacyanoferrates.\(^{(84)}\) Fluorine-sensitive electrodes have been applied for a number of kinetic determinations. The determination of carbocysteine in colored pharmaceuticals based on monitoring of its reaction with 1-fluoro-2,4-dinitrobenzene, catalyzed by
hexamethyltrimethylammonium bromide micelles, was performed using a $F^-$-selective electrode. \(^{(85)}\) The same type of electrode was used for kinetic determination of ethylenediaminetetraacetic acid (EDTA) and citrate by the displacement of fluoride from aluminum(III) fluoride complexes. \(^{(86)}\) A kinetic method based on a fluoride-selective electrode was applied in the determination of alkaline phosphatase in serum. \(^{(87)}\) Kinetic determination of primary and secondary amines was accomplished based on their reaction with 1-fluoro-2,4-dinitrobenzene monitored by an $F^-$-selective electrode. \(^{(88)}\)

Copper was determined based on its catalytic effect on the reaction between hexachloroantimonate and hydroxylamine. The rate of the reaction was measured potentiometrically with an Sb(V) ISE using 1,2,4,6-tetraphenylpyridinium iodide as electroactive material in a poly(vinyl chloride) (PVC) membrane. \(^{(89)}\) A Pb ISE was used for determination of citrate by monitoring the citrate in drinks and pharmaceutical products. The method is based on inhibition, by citrate, of crystalline growth of lead carbonate seed crystals. \(^{(90)}\)

**Amperometric detection** involves monitoring the current between a working electrode and an auxiliary electrode at a given potential difference between the working and a reference electrode. The working electrode could be metal (Pt, Co, W), modified metal (metal hexacyanoferrate, Pt enzyme) or carbon-based (vitreous carbon, graphite, carbon paste, modified carbon paste). The auxiliary electrode is Pt, a carbon-based electrode or sometimes metallic parts of a cell. The reference electrode is Ag/AgCl or a saturated calomel electrode (SCE). The potential of the working electrode is a function of the species to be measured and of the type of electrode. Detection limits are in the range of 1 µM. Lower detection limits could be achieved with chemically modified electrodes. Detection cells could have a volume in the range of microliters.

Amperometric detection has been extensively used in conjunction with rotating bioreactors. The cell comprises a stationary Pt-ring electrode, a stainless-steel auxiliary electrode and an Ag/AgCl reference electrode. \(^{(91)}\) It was used for determination of glucose, via the $\text{H}_2\text{O}_2$ produced enzymatically, kinetic determination of fructose and ascorbate in food, \(^{(92)}\) determination of choline esters in pharmaceuticals, \(^{(93)}\) and in comparative studies of bioreactor systems. \(^{(94)}\) An amperometric oxygen sensor with a Pb anode, an Ag cathode and a polyelectrolyte membrane was used for the determination of $\text{O}_2$ by measuring the rate of its reaction with dissolved oxygen. \(^{(95)}\) For kinetic determination of As(III) the limiting diffusion current is measured, in a solution of KBr and KIO$_4$, with a polarograph with a Pt indicator electrode at 0.4 V and an SCE. The oxidation of KBr by KIO$_4$ is subject to an induction period, the length of which is directly proportional to the As(III) concentration. \(^{(96)}\) Hg could be determined based on its catalytic effect on the photooxidation of EDTA by iodine. The reaction rate is measured amperometrically from the time required for the iodine reduction current to decay to zero at $-100 \text{ mV}$ vs SCE. \(^{(97)}\) The determination of nitrate is based on the same photochemical reaction as above, but with an inhibitory effect. A platinum indicator electrode and an SCE is dipped into the EDTA and iodine solution and the current–time curve is recorded at a constant potential of 100 mV. \(^{(98)}\)

**Biamperometric detection** is based on the measurement of current between two identical electrodes. The detector is simpler than in amperometric detection and consists of two opposing platinum electrodes in contact with the carrier stream. A potential difference of 10–500 mV is applied between the electrodes and the resulting current is measured. The current can flow only when both reduced and oxidized forms of a couple are present in the cell. The detection limits are in the range of 1 µM. Biamperometric detection was used in the kinetic determination of vitamin B$_1$ during their reaction with coulometrically generated iodine. \(^{(99)}\)

For **conductometric detection**, a computer-controlled bipolar pulse conductivity system has been developed for use as a detector in reaction rate determinations. The system could perform discrete conductance measurements in 30 µs and could be used as detector in stopped-flow studies. \(^{(6)}\) **Kinetic monitoring based on conductometry** was applied to the synthesis of $N\alpha$-benzyloxycarbonylalanylphenylalaninamide in the presence of *Pseudomonas aeruginosa* elastase. After the reaction was initiated the change in conductance was recorded allowing a precise measurement of the initial reaction rate. \(^{(100)}\) A conductometer with facilities for conductivity compensation was used to monitor the bromate–iodide–ascorbic acid Landolt reaction. The time interval between the initial rise in conductivity on mixing the solutions and the attainment of a minimum conductivity value was taken as the reaction time. \(^{(101)}\)

The effect of lanthanide ions on the kinetics of glutamate dehydrogenase with NADH as coenzyme was monitored with a **chronoamperometric method**. The initial reaction rate, and hence the activity of glutamate dehydrogenase, was determined by measuring the decrease in the steady-state limiting current of NADH oxidation at a vitreous C electrode at $\pm 0.8 \text{ V}$ vs SCE. \(^{(102)}\) **Chronopotentiometry** with a Br$^-$/selective chalcogenide glass electrode was applied in the kinetic determination of vanadium in natural waters and wastewater. \(^{(103)}\)

**Polarographic-based detection** was used for catalyzed reactions with the reaction step and detection step performed separately. The catalyzed reaction is quenched after a fixed time. The concentration of one of the
species involved in the reaction is determined by a form of polarography. This procedure was applied to the determination of ascorbic acid and Fe(III) using single-sweep oscillography\(^\text{104,105}\) and nitrate by differential-pulse polarography\(^\text{106}\) with a dropping-mercury electrode as the working electrode and a Pt counter electrode.

3.1.2 Photometric Monitoring

Photometric monitoring makes up the bulk of detection systems used in reaction rate determination, as demonstrated in the comprehensive reviews by Mottola et al., dedicated to kinetic determinations, published biannually in \textit{Analytical Chemistry}.\(^\text{107–109}\)

Photometric systems for measuring ultraviolet and visible absorbed, fluorescent or chemiluminescence radiation are equipped almost exclusively with photomultiplier tubes or photodiodes (PDs). Both of these transducers have a response time in the nanosecond range, allowing very fast reactions to be followed. The type and model of transducer selected for a given type of chemical system and spectroscopic method should provide the highest signal-to-noise ratio. Photomultiplier tubes exhibit better characteristics than PDs when low light levels are measured (photocathodic current below \(10^{-9}\) A) and are recommended for measurements requiring a narrow absorption bandwidth and for fluorescence, phosphorescence and chemiluminescence spectroscopy.\(^\text{110}\) PDs are advantageous for the measurement of higher light intensities as in molecular absorption spectroscopy where the large bandwidth allows the use of filters or monochromators with larger bandwidth.\(^\text{111}\)

Most detection systems are commercially available spectrophotometers, which could be used, for slow reaction, with no major modification. For spectrophotometers used as a detection system in flow analysis, a flow-through cell should be adapted to the cell compartment of the spectrophotometer.

A series of flow-through cells were used in connection with colorimeter heads using light-emitting diodes (LEDs) as light sources and PDs as detectors. Such a colorimeter head is very cheap, has a small volume and does not require very stabilized sources. The band gap in LEDs could be altered in the manufacture so that LEDs having source peak emission at different wavelengths in the visible region are currently available. The LED emission band-pass is less than 15 nm at half emission peak height, which is comparable to the band-pass of an interference filter. Such a colorimeter head was built in a double-beam version with an LED of appropriate wavelength and two PDs. One PD is mounted in the light path and the other perpendicular to the path. A beam splitter fabricated from a rod cut at one end at a 45° angle reflects about 50% of the light to the detecting PD while the remainder of the light strikes the reference PD.\(^\text{112}\)

3.1.3 Fluorimetric and Chemiluminescence Monitoring

Fluorimetric and chemiluminescence monitoring implies the detection of relatively low light intensities. Most commercial spectrophotometers are provided with facilities to measure both fluorimetric and chemiluminiscence signals.

\textit{Fluorimetric detection} is a multiparameter technique that involves an absorption wavelength and a luminescence wavelength. The bandwidth and the polarization of both light beams could be separately controlled. This, in combination with the control of other parameters, such as beam modulation, provides the fluorimetric methods with a high selectivity.\(^\text{113}\)

Fluorimetric monitoring in reaction rate methods has been applied for both catalyzed and noncatalyzed reactions. Kinetic fluorimetric determination has been reported for a number of metallic ions, e.g. iron,\(^\text{114}\) cerium,\(^\text{115}\) aluminum,\(^\text{116}\) tin,\(^\text{117}\) nickel\(^\text{118}\) and vanadium.\(^\text{119}\) The combination of stopped-flow or flow injection in the stopped-flow mode and fluorimetric monitoring of reaction rate has been used for pharmaceuticals, drugs, pesticides and biological samples.\(^\text{8,120–126}\) The potential of reaction rate methods in pesticide and drug determinations was demonstrated by using stopped-flow immunoassay. The negative effect of the sample matrix could be avoided by monitoring the initial rate of an antigen–antibody reaction. Using fluorescence polarization as the detection system significantly enhances the selectivity of the method.\(^\text{127–129}\) In this case, a polarizer polarizes the excitation beam while a second polarizer is introduced in the luminescence beam. Light intensity measurements could be made parallel or perpendicular to the polarization of the exciting light.

\textit{Chemiluminescence detection} in reaction rate measurements involves a highly efficient system of mixing and a fast light detector that are motivated by the transient nature of the light emitted by chemiluminescent systems. This is why this type of detection is used in conjunction with stopped-flow techniques or continuous reagent addition coupled with spectrophotometers. Chemiluminescence detection was used for the determination of nitrogen oxides in environmental samples, based on NO–O\(_3\) chemiluminescence\(^\text{130}\) and in studies of the effects of surfactants on the rate of peroxyoxalate chemiluminescence reaction between bis[N-[2-(N'-methyl-2'-pyridiniumyl)ethyl]-N-[(trifluoromethyl)sulfonyl]loxamide, H\(_2\)O\(_2\) and a fluorophore.\(^\text{131}\) Also, in the determination of serum creatinine using creatinase, creatinase and sarcosine oxidase, the detection was based on the chemiluminometric rate assay of H\(_2\)O\(_2\) produced.\(^\text{132}\)

The continuous addition reagent technique was tested
for the Cu(II)-catalyzed reaction between luminal and H₂O₂ using a fluorimeter in energy mode at 425 nm for chemiluminescent reaction-rate determinations.\(^{(60)}\) A stopped-flow procedure combined with chemiluminescence detection was reported for multicomponent kinetic analyses of chemiluminescence enhancers (protocatechuic and caffeic acids).\(^{(133)}\) The chemiluminescence of the bis(2,4,6-trichlorophenyl) oxalate–H₂O₂ system was used for the kinetic determination of phenothiazine drugs. The method was applied to the determination of acepromazine in horse plasma.\(^{(60)}\) Chemiluminescence detection was used for the determination of alkaloids (psychotropic indole derivatives) by the maximum reaction rate method. An application of psilocin determination in mushrooms has been reported.\(^{(134)}\) A kinetic method for tertiary aliphatic amines with chemiluminescence detection is based on the reaction between tertiary aliphatic amines and sodium hypochlorite in alkaline medium and in the presence of fluorescein as sensitizer. The chemiluminescence intensity was monitored using a photomultiplier at a rate of one reading every 7.5 ms. Detection limits were 2.7–7.7 mol. The method was applied to determine trimethylamine in fish and to study the degradation of fish during storage.\(^{(67)}\)

**Photon counting**, as a detection technique fitted for very low light intensities, has been used in fluorimetry for drug determinations. A stopped-flow reactor was used in conjunction with a photon-counting spectrofluorimeter, equipped with a xenon-arc source, for the determination of nordazepam in urine and imipramine in blood serum.\(^{(127)}\)

### 3.1.4 Other Types of Detection

**Thermometric detection** could be used for catalytic reactions. After the start of reaction the initial temperature change is usually proportional to the catalyst concentration if the reaction is first order with respect to the catalyst. The temperature of the reacting mixture is monitored using a thermistor connected to a Wheatstone bridge and having a sensitivity of 0.01 °C/mV. Thermometric detection requires simple instrumentation and avoids interference from colored compounds and precipitates. Reaction rate determination by thermometry has been applied to the determination of single elements\(^{(135–142)}\) and mixtures of elements\(^{(143–145)}\) based on their catalytic effect in redox reactions and for the determination of enzymes.\(^{(146)}\)

**Surface acoustic wave** (SAW) sensors are mass detectors that can measure a variety of other physical properties at the sensor surface. Most SAW devices consist of a piezoelectric crystal with two sets of interdigital transducers laid down on the crystal surface. When a time-varying radiofrequency potential is applied to one set of interdigital transducers, an acoustic wave is launched in the surface of the piezoelectric crystal. This wave travels across the surface of the crystal and is received by the second set of transducers, which converts the mechanical energy of the wave back into an electrical signal. The acoustic wave generated is very sensitive to material present at the crystal surface. The acoustic device is converted into a chemical sensor by application of chemically selective layer on the resonant crystal. The resonant frequency of the SAW device would be altered if a chemical component interacts with the selective layer.\(^{(147)}\)

The use of SAWs in analysis is increasing because of their selectivity and sensitivity. In recent years a series of applications of SAW as detectors have been published for kinetic determinations of alkaline phosphatase and acid phosphatase, \(^{(148,149)}\) trypsin and antitrypsin in human serum, \(^{(150,151)}\) pancreatic lipase, \(^{(152)}\) urea in human blood, \(^{(153)}\) arginase–urease, \(^{(154)}\) organophosphorus nerve agents \(^{(155)}\) and organophosphorus pesticides.\(^{(156)}\)

### 3.2 Multichannel Detection

Multichannel detection is the basis for multidimensional instrumentation. It offers a great deal more information about time-dependent systems than could be obtained from monitoring one signal versus time. Multichannel detection is accomplished mainly as photometric detection based on photodetector arrays. Such an array consists of a number of small photosensitive detectors, called pixels, which are part of a single integrated circuit. The array could be linear or two-dimensional. Typically, a linear array could have from 64 to 4096 photosensitive elements on a photoactive surface 2.5–50 mm long and a few millimeters wide. Linear arrays with 8196 elements are also known. A two-dimensional array could have from 64 × 64 to 4096 × 4096 pixels. The pixel size ranges from 9 to 27 μm. The sensitive element could be a PD, charged-coupled device (CCD) or charge-injection device (CID). Most arrays have a spectral responsivity from 200 to 900 nm but devices that respond from 1 to 1000 nm are also available.\(^{(157)}\)

By placing the photodetector array in the focal plane of a spectrometer, each element provides the information for a different wavelength and a full spectrum in absorption, fluorescence or chemiluminescence mode could be obtained in a matter of milliseconds or less. This allows for the monitoring of multiple species, observation of transient intermediates and correction for background absorbances. An example of a time–wavelength recording using diode arrays is given in Figure 12 for the iron-catalyzed reaction between leucomalachite green and peroxodisulfate.\(^{(158)}\) The absorbance peak on the left indicates a catalytic effect produced by iron(II) and the higher peak in the middle a catalytic effect of both iron(II) and iron(III).
Two types of spectra, absorption and fluorescence, could be also obtained simultaneously. A bifurcated fiber-optic light pipe and a spectrograph with an intensified array detector are used. The measurement circuit is operated in the time-sharing mode so that a single array collects both the absorbance and fluorescence signals. Spectrofluorimeters in a T format configuration could be used for the simultaneous determination of two species. In order to avoid spectral overlap the method requires that the reaction products of the analytes have similar excitation wavelengths and very different emission wavelengths. The fluorescence intensity, provided by the same measurement cell, could be read on two channels perpendicularly on the excitation beam, at two different wavelengths. An appropriate set of filters and monochromators could be used to provide the excitation wavelength and the emission wavelengths. Since in most instruments there is only one emission monochromator, the wavelength of the second emission arm is set by a filter. This experimental set-up was used for simultaneous determination of nordazepam and imipramine in blood serum, for neomycin and promethazine in pharmaceutical preparations and for ampicillin and tetracycline in milk, by stopped-flow fluorimetry. The photodetector arrays could be used for position-resolved observation. The detector is placed in a parallel position along the observation cell of a continuous-flow system. The data collected at different points along the cell by each element of the array correspond to different reaction times. This method of observation is exemplified in Figure 13 for a PAF spectrometer.

3.3 Combined Detection

The rate measurements are more susceptible to variations in experimental conditions than equilibrium-based measurements. Combined detection could be used to minimize the effect of different parameters on the precision of rate measurements. Instead of maintaining the experimental conditions perfectly constant, the parameters that influence the precision could be measured and then a normalized rate calculated. An instrumental set-up for monitoring fluorescence signal, temperature and pH is given in Figure 14. The fluorescence signal is simultaneously monitored with temperature and pH, the main experimental factors that could influence the precision of reaction rate measurements.

By means of dedicated software, the measured rate is normalized to a value that would be obtained at predetermined temperature and pH values. By applying the software correction the precision of rate measurement improves with a factor of four for temperature variations.
higher than 1 °C and more than one order of magnitude for a pH variation greater than 0.28.

Specialized spectroelectrochemical detectors for flow injection were built so that absorption spectra could be recorded simultaneously with potentiometric measurements. In one of these systems, \cite{163} the cells have a rectangular flow channel of 15 × 5 mm with a reticulated vitreous-carbon working electrode, an Ag/AgCl reference electrode and an open optical window. The dead volume of the cells is 80 µL. Absorption spectra were recorded with a 2-nm slit width and a 2-s response time.

Table 1 Classification of kinetic methods of analysis based on data processing procedures. \cite{164} classified, in a broadly applicable scheme, the options available in processing the reaction rate data. A simplified version of this classification is presented in Table 1. For single-component methods the classification scheme has two main categories: direct computation methods and curve-fitting methods.

4 DATA HANDLING

The final step of a kinetic method of analysis is the determination of the analyte concentration based on the reaction rate measurement. In turn, the reaction rate is obtained by processing the signal provided by the reaction monitoring system.

In the first stages of the data processing the slope of the signal (or the slope of the tangent to the signal) should be determined. In some analytical systems the rate curve is recorded and the slope is determined, by various means, from this recording. However, for many routine analyses, the recording of a rate curve could be a tedious or an unnecessary operation. Therefore, simpler ways to extract the kinetic information were devised, so that one or a few data from the detector are sufficient for a point on the calibration curve.
The methods in the first category include those that could be implemented by manual data manipulation and automation with analog electronic devices. The data that represent the analytical signal are used to compute the concentration directly. The second category was developed after the advent and the wide availability of low-cost computers in analytical chemistry and involves curve-fitting procedures.

4.1 Direct Computation Methods

4.1.1 Integral Methods

The integral methods subcategory includes some basic methods that were applied from the early stages of kinetic determination development: fixed-time and variable-time methods. A schematic representation of the principle of these two methods is given in Figure 15(a) and (b), respectively.

4.1.2 Fixed-time Method

In the fixed-time method, the change in the reaction-monitor signal is measured over a predetermined time interval, $\Delta t$. The method could be implemented in making the signal measurement at one point, two points or multiple points. The fixed-time method has two main attractive features. The first is that the measured signal varies in direct proportion to the analyte concentration. If the signal is a linear function of concentration, such as absorbance in spectrophotometric detection, the signal change over $\Delta t$ varies linearly with concentration. This makes the data much easier to process and the concentration could be computed using just a multiplication factor. The second attractive feature is related to the fixed interval of time used for measurement. It is more convenient to automate the method if a fixed time sequence is used. In manual processing of a large number of samples, a fixed-time method facilitates the sample processing sequence, so that the signal could also be measured in a sequence.

However, in applying the fixed-time method, the relationship between signal and concentration should be known exactly. Anything that affects this relationship should be taken into consideration for the full range of analyte concentration implied in the determination. The method is less attractive in the case of detectors that do not respond linearly with concentration.

In the one-point approach of the fixed-time method, the time interval for measuring the signal is considered from the origin of the rate curve. It is the simplest form of data processing, since a single measurement is made, but it has the disadvantages of not compensating for a fixed background or for curve nonlinearity. In the two-point mode, two signal measurements are made with a $\Delta t$ time interval.

![Diagram of fixed-time methods](image)

**Figure 15** (a) Fixed-time and (b) variable-time methods exemplified on a pseudo-first-order reaction.
The signal difference, \( \Delta S \), for the two measurement points is used to compute the concentration. In comparison with the one-point approach, the two-point mode could compensate for the fixed background. However, it cannot detect the curve nonlinearity. The multiple-point approach implies the measurement of the signal difference between multiple points in time. The main merit of this approach is that it can detect nonlinear responses.

### 4.1.3 Variable-time Method

The variable-time method involves the measurement of the time required by the reaction-monitor signal to change by a predetermined amount. The reciprocal of the measured time interval is proportional to the concentration of the sought-for species. Unlike the fixed-time methods, here is not necessary to know the mathematical relationship between concentration and detector signal and the nonlinearity of the detector response is of little importance. The detection system should be sensitive enough to detect the predetermined reference point(s).

Among the disadvantages of the method is the fact that the measured parameter, the time interval, varies inversely with the analyte concentration following a relationship that is relatively complex except for zero-order reactions. Since the time for a reaction to reach a predetermined signal level is not predictable, it is less convenient to use the variable-time method for manually processing a large number of samples or for automation. In some cases the concentration of the sought-for species could be too small and the detector signal could not reach the predetermined level. This sets a limit for the lower concentration that could be determined in a convenient time span. Also, the systems using the variable-time method are more susceptible to random spikes of the signal that may cause false triggering of the measurement system.

The one- and two-point approaches could be applied for the variable-time method. Their relative merits and shortcomings are the same as for the fixed-time method.

### 4.1.4 Rate Methods

This category includes the methods in which the rate is determined instantaneously direct from the detector signal.\(^{(168)}\) They could be considered as *derivative methods* since the electronic device used for rate determination is a derivative circuit. The circuit is very simple and provides the instantaneous value of the tangent at one point of the rate curve. Paradoxically, this is a limiting factor because at the required sensitivity for rate measurement the rate curve is accompanied by noise. The instantaneous slope of the noise is usually much greater than that of the signal and the final result is an amplification of the noise signal.\(^{(9)}\)

### 4.1.5 Integrated-signal Methods

Integrated-signal methods use the integral of a portion of the rate curve. In the only method from this group the detector signal is integrated on two equal segments of the rate curve.\(^{(169)}\) The integrated curve portions could be adjacent or separated by a certain time interval. For zero-order processes the difference between the integrated signals is proportional to reaction rate. The principal advantage of this approach is very low noise susceptibility. This particular method could be considered a form of fixed-time two-point method in which the noise is averaged by integration.

Neither rate methods nor integrated-signal methods have been used extensively in routine applications. One of the reasons is that their implementation requires a specialized device, a ratemeter. Also, integral methods, fixed-time or variable-time, were more convenient for routine analysis since they could be applied by simply reading the level of the detector signal or measuring an interval of time. An integrated-signal method that offers greater noise immunity and reliable results was developed at about the same time when the use of computers was expanding in analytical instrumentation. The principle of the method could be implemented much more easily by software so there was no reason to develop specialized instrumentation.

### 4.2 Curve-fitting Methods

The methods in this category are based on in-line or off-line data processing by a computer. Unlike direct computation methods, where the reaction rate is obtained by using a closed-form algorithm applied to a few experimental points, here a mathematical model is computed that represents the “best fit” of data obtained from the detector. The values of the parameters required by the kinetic determination are obtained from the equation that resulted from the fit. The curve-fitting procedure could be applied for either linear or nonlinear responses.

**Linear responses** are the commonest applications since they correspond to zero-order and pseudo-zero-order processes that are most frequent in kinetic determinations. A least-squares algorithm or a Kalman filter could be used.\(^{(170,171)}\) Several well-known software packages such as ORIGIN\(^{\text{®}}\) (Microcal) and EXCEL\(^{\text{®}}\) (Microsoft) include a linear regression fitting option. In addition to obtaining the slope of the rate curve, which is the primary objective of the method, some other statistical parameters could be computed: intercept linearity, correlation coefficients and errors.\(^{(172)}\)

The curve-fitting for *nonlinear responses* could be used to compute directly the concentration from the slope. The slope could be determined either at the reaction...
INSTRUMENTATION FOR KINETICS

beginning, where it approaches zero-order behavior, or at another point on the rate curve. In the former case the data manipulation is reduced to that of a linear response. In the latter case the concentration could be computed from the slope if some of the experimental parameters are kept constant. For a first-order reaction this means that the slope is always measured at the same point in time and the rate constant does not change during the reaction.

The curve-fitting procedure could be used in a predictive manner. The kinetic curve based on data collected in one stage of the reaction could be extrapolated to another time range, without the need to run the reaction to completion. It is possible to predict the value of absorbance corresponding to the steady state in a spectrophotometrically monitored reaction or the steady-state velocity from data collected before the steady state was achieved.\(^{173-175}\)

Data processing by computer offers the possibility to apply error-compensating methods to overcome the sensitivity of kinetic methods to conditions that influence the rate constant and to implement multicomponent kinetic methods.\(^{176}\) Details of these features of data processing step of kinetic methods are given in the article Data Treatment and Error Analysis in Kinetics.

Luminescence-based kinetic determinations are of great analytical interest and flexibility as they combine the high selectivity of kinetic methodology with the low detection limits afforded by the different luminescence techniques.

1 INTRODUCTION

Luminescence techniques can be included among monitoring techniques for kinetic determinations. However, the typically high selectivity and low detection limits of the ensuing methods make them especially attractive for kinetic analysis, where measured concentration changes are usually quite small. Like other kinetic methods, the growth of luminescence-based kinetic methods has relied heavily on the availability of suitable instrumentation. Thus, many reaction rate methods were initially less precise and more time-consuming and tedious than conventional equilibrium methods because the reaction rate had to be manually extracted from the recorder tracing, which decreased the precision of the results and increased the data treatment time. In addition, the instability of luminescence instruments precluded wider use of dynamic measurements based on using luminescence detection. These problems have been overcome with the inception of electronic devices and computers that permit the automated acquisition of data as the process develops, and afford enhanced data handling. The availability of stable luminescence instruments, automated precise sample and reagent delivery systems, and improved temperature-control equipment has minimized the shortcomings of luminescence-based kinetic determinations, which are now effective alternatives to equilibrium determinations as shown by the abundant literature on their applications.

The use of dynamic luminescence measurements affords very low detection limits (better than those obtained with equilibrium methods in some instances). Thus, when a luminescent system yields a static background signal, which is very usually the case in analyses of real samples, discriminating it from the equilibrium analytical signals obtained at very low analyte concentrations can be difficult because both are static signals. However, when the reaction rate is used as the analytical parameter, its dynamic character makes it less strongly dependent on the background signal provided this does not change with time. Also, analytical measurements made at the beginning of the reaction are known to avoid or minimize the potential inhibitory effect of other constituents of the sample matrix.

The first reported application of the combination of luminescence techniques and kinetic methodology was the fluorimetric monitoring of initial reaction rates for the determination of the rate constants involved in the association and dissociation of flavin mononucleotide (FMN) with its apoenzyme.\(^1\) The study, which was carried out by using a filter fluorimeter, led to the development of many luminescence-based kinetic methods available today. Early fluorimetric reaction rate methods were reviewed by Ingle and Ryan in 1981,\(^2\) who noted the scant practical use of kinetic fluorimetric methods. However, continual improvements in available equipment have helped to consolidate fluorimetry and other luminescence techniques to be consolidated as alternatives to the analysis of real samples using kinetic methodology.

Broadly speaking, luminescence-based kinetic determinations can be classified into four groups, as follows.
1. Determinations based on the rate of change of chemical composition with time, which is monitored by measuring the variation of the luminescence signal with time. These determinations involve the use of conventional kinetic approaches such as the tangent, fixed time, and fixed signal (or variable time) methods.\(^4\) Determinations based on measurements of the induction period, which arises in Landolt reactions\(^4\) are also included in this group.

2. Determinations based on the use of flow systems with luminescence detection. Measurements are obtained when neither physical (homogenization) nor chemical equilibrium has been attained by the time that the sample zone reaches the continuous detector, so these determinations are doubly kinetic in nature.

3. Determinations based on measuring the lifetime of the excited state of a chemical species, which is obtained as the molecules return from the excited state to the ground state.

4. Determinations based on the use of chemiluminescence (CL) reactions in which the intensity of the emitted light is recorded as a function of the time and the peak intensity or the integrated area under all or part of the intensity–time curve is used as the analytical parameter.

The different luminescence techniques are included in the first and second group as they are used only as detection systems; by contrast, those in the third and fourth group unavoidably involve two luminescence processes: photoluminescence (fluorescence or phosphorescence) and CL. All these determinations involve making analytical measurements while the system is under nonequilibrium conditions, so kinetics play a significant role. Although each group is commented on to some extent here, this chapter deals mainly with traditional kinetic determinations,\(^5,6\) i.e. those in the first group, which also includes CL and flow methods based on kinetic methodology. For a more systematic discussion, they have been classified according to the luminescence process involved. The special features of immunoassay and automation justify coverage in separate sections. The last section describes selected examples of simultaneous determinations.

2 THEORETICAL PRINCIPLES

All luminescence phenomena are processes of an intrinsically kinetic nature as they involve the emission of ultraviolet, visible or near-infrared radiation from a molecule or an atom resulting from the transition of an electronically excited state to a lower energy state (usually the ground state). Thus, in photoluminescence processes, which involve the use of electromagnetic radiation as the exciting source and the transition from a singlet (fluorescence) or a triplet (phosphorescence) electronically excited state, measurements are carried out under conditions of dynamic change controlled by the rates of deactivation processes that follow the excitation. Figure 1 shows the typical rate constants for the different excited state processes.

The excited states responsible for luminescence phenomena have finite lifetimes that can be measured by applying time-resolved methodologies and used as additional analytical parameters. In principle, time-resolved measurements contain more information than do steady-state measurements, since steady-state values represent the time averages of time-resolved determinations. The temporal information given by the fluorescence or phosphorescence lifetime can be employed, usually in combination with other parameters, to identify compounds. Also, if two or more luminescent compounds have similar absorption and emission spectra but different luminescence decay times, the compounds can be distinguished from one another by differential kinetic analysis.

In general, the excitation of a luminophore with an infinitely short pulse of light provides the best approach to explaining the luminescence decay. The variation of
the luminescence intensity as a function of time after the excitation pulse is applied is assumed to conform to an exponential decay curve, since the luminescence decay process usually obeys first-rate kinetics (Equation 1):

$$I_t = I_0 e^{-kt} = I_0 e^{-t/\tau}$$  \hspace{1cm} (1)

where $I_t$ is the luminescence intensity at time $t$, $I_0$ is the maximum luminescence intensity during excitation and $\tau$ is the time after removal of the exciting radiation. Parameter $k$ is the first-order rate constant for the decay process and equals the reciprocal of the mean lifetime of the excited state, $\tau$. When $t = \tau$, the luminescence intensity is equal to 1/e of its initial value. Thus, the luminescence lifetime is the time required for the luminescence intensity to decrease to 1/e of its initial value.$^{[7]}$ Experimental lifetimes, whether for fluorescence or phosphorescence, indicate the overall rate at which the excited state is deactivated, through both radiative and nonradiative processes.$^{[8,9]}

The intrinsic luminescence lifetime, $\tau_0$, can be experimentally obtained, provided luminescence is the only mechanism by which the excited molecule returns to the ground state. For a fluorescent process, the relationship between $\tau_F$ (observed fluorescence lifetime) and $\tau_{F0}$ (intrinsic luminescence lifetime) is given by Equation (2):

$$\tau_F = \phi_F \tau_{F0}$$  \hspace{1cm} (2)

where $\phi_F$ is the fluorescence quantum yield, which can be defined in terms of rate constants of fluorescence ($k_F$), internal conversion for lowest excited singlet state ($k_I$) and intersystem crossing ($k_{IS}$) as in Equation (3):

$$\phi_F = \frac{k_F}{k_F + k_I + k_{IS}}$$  \hspace{1cm} (3)

Also, $\tau_F$ can be defined as a function of such rate constants (Equation 4):

$$\tau_F = \frac{1}{k_F + k_I + k_{IS}}$$  \hspace{1cm} (4)

If a biomolecular quenching process were competing for fluorescence, then the term $k_Q[Q]$ would be added to the denominator, where $k_Q$ is the rate constant for biomolecular quenching and $[Q]$ the concentration of quencher.

Similar expressions can be obtained for phosphorescence decay, but the relationship between the quantum yield ($\phi_P$) and intrinsic ($\tau_{P0}$) and observed ($\tau_P$) lifetimes is different in this instance, as the triplet formation quantum yield ($\phi_T$) must be also included, as in Equation (5):

$$\tau_P = \frac{\phi_P \tau_{P0}}{\phi_T}$$  \hspace{1cm} (5)

where $\phi_P = [k_P/(k_P + k_M)]/[k_{IS}/(k_{IS} + k_I + k_F)]$, in which $k_M$ denotes the intersystem crossing between the lowest triplet state and the ground state rate constant, and $\phi_T = k_{IS}/(k_{IS} + k_I + k_F)$. Thus, $\tau_P$ is given by Equation (6):

$$\tau_P = \frac{1}{k_P + k_M}$$  \hspace{1cm} (6)

Additionally, if a quenching process were present, the term $k_Q[Q]$ would be added to the denominator, as in fluorescence. The situation would also be more complex if other phenomena such as photochemical or energy transfer processes were present.

Phosphorescence triplet states of organic molecules usually have relatively long mean lifetimes (at the level of milliseconds or greater), so measuring $\tau_P$ is fairly simple and can be accomplished with conventional commercial phosphorescence spectrometers. However, $\tau_T$ is much shorter, at the level of $10^{-8} - 10^{-11}$ s, and its measurement is electronically a much more difficult task. Two general approaches to determining the phosphorescence lifetime have been developed that are named time-resolved and phase-resolved methods, and are based on the use of two different types of techniques, namely: pulse fluorimetry, which relates measurements performed in the time domain; and phase and modulation fluorimetry, which relate to the frequency domain.$^{[10,11]}

With CL, where the molecule in the electronically excited state is produced by a chemical, biochemical (bioluminescence) BL or electrochemical (electro luminescence) reaction, the process is probably the most markedly kinetic among luminescent phenomena, as the emission intensity, $I_L$, in photons emitted per second, is directly proportional to the rate of the reaction involved, $dC/dt$, in molecules reacting per second, according to Equation (7):

$$I_L = \phi_L \frac{dC}{dt}$$  \hspace{1cm} (7)

where the proportionality constant $\phi_L$ is the CL quantum yield or efficiency, in photons emitted per molecule reacting. The CL efficiency is the product of the excitation quantum yield, $\phi_{EX}$, in excited states produced per molecule reacting, and the emission quantum yield, $\phi_{EM}$, in photons emitted per excited state. Efficiencies ranging from $10^{-15}$ to nearly 1 have been observed. Higher values are usually associated with BL reactions; by contrast, the conventional CL reactions usually employed for analytical purposes have typical efficiencies of $0.001 - 0.1$.\(^{[12]}\)

Although the lifetimes of the excited singlet states that are responsible for CL emission have typical durations in the nanoseconds region, the emission of light persists for as long as the CL reaction takes place. Thus, the photophysics of the electronically excited
products of the reaction and the kinetics of the reaction are involved in the CL emission. This justifies the prominent role assigned to CL methods among kinetic-based approaches. In fact, two of the more important factors to be considered in developing a CL method are the efficiency of the CL reaction, which ultimately affects sensitivity and detection limits, and the reaction kinetics, which dictates precision and throughput. In practice, both parameters are affected by experimental conditions including solvents, concentrations, pH, and reagent purity.

3 PHOTOLUMINESCENCE

In addition to the fact that all fluorescence and phosphorescence methods are intrinsically kinetic in nature, both luminescence processes have been applied to reaction rate methodology, but fluorescence-based kinetic determinations are much more numerous than those involving phosphorescence measurements. Overall, phosphorescence analysis has not been so widely used as fluorescence analysis, owing to the special requirements of the former, which originally called for cryogenic solvents and liquid nitrogen temperature, and later for the immobilization of phosphors adsorbed on solid matrices. However, the inception of micelle-stabilized room-temperature phosphorimetry (MSRTP), which uses heavy atoms, has promoted the use of phosphorimetry as a determination tool.

3.1 Fluorescence

Fluorimetry has so far been the luminescence technique most frequently applied to reaction rate methodology. It is a competitive alternative to photometric and electrochemical measurements when fluorescent species are involved, as it generally affords better detection limits and selectivity, and wider dynamic ranges. Thus, detection limits can be two or three orders of magnitude lower than those obtained with photometric detection. Even if the chemical system involves no fluorescent species, fluorimetry can still be used as the detection system by coupling with a fluorogenic species in a secondary indicator reaction, as in a number of reported enzymatic determinations. Thus, a generic enzymatic reaction can be represented by Equation (8):

\[ S + E \rightarrow P + E \]  

(8)

where S is the substrate, E the enzyme and P the product, and any of them is fluorescent. An indicator reaction can be coupled, as in Equation (9):

\[ P + R + E' \rightarrow P' + R' + E' \]  

(9)

Advances in instrumentation have also been applied to enzymatic kinetic analysis. Thus, an integrated microfabricated device that performs automated enzymatic analysis has been reported. Electrokinetic flow was used to control the dilution and mixing of reagents, and the β-galactosidase-catalyzed hydrolysis of resorufin β-D-galactopyranoside, which is hydrolyzed to the fluorescent resorufin, was used as a model system for enzyme kinetic determination. The microchip design used is shown in Figure 2. An enzyme assay performed on the microchip within a 20-min period required only 200 pg of enzyme and 7.5 ng of substrate, thus reducing the amount of
reagent needed by four orders of magnitude relative to a conventional assay.

Methods for the determination of inorganic species based on fluorimetric reaction-rate measurements are relatively abundant.\textsuperscript{5,6,16,17} Many are based on the use of redox reactions, where the inorganic species acts as a catalyst. This methodology has allowed the very sensitive determination of metal species such as iron and cobalt, which cannot be determined by other fluorimetric approaches, owing to their paramagnetism. Other determinations are based on activation or inhibition processes, using enzymatic reactions in some cases. The main shortcoming of many of these methods, particularly earlier ones, is that they were not applied to real samples. Also, the number of kinetic fluorimetric determinations for inorganic species reported in the last years has declined markedly. Kinetic methodology has scarcely been used in connection with complex formation reactions owing to their high rates, which are usually measured by using fast-mixing systems.

Fluorimetric determinations of organic compounds based on kinetic methodology generally involve uncatalyzed reactions. These reactions are as varied as the nature of the organic compounds themselves,\textsuperscript{5,6} although oxidation and condensation reactions are the most commonly used. There has been a trend to automating these methods in recent years in various analytical fields, including clinical, pharmaceutical, environmental and food analyses. Although most kinetic fluorimetric methods utilize a reaction monitoring system that produces a single signal that is proportional to the reactant or product concentration, modern multidimensional instrumentation allows much more complete information about the chemical system to be derived. Thus, array detectors provide fluorescence spectra in a time short enough to be useful for extracting kinetic information with a view to monitoring multiple species, observing transient intermediates, obtaining information about species with overlapping spectra and correcting for background fluorescence.\textsuperscript{12} Multidimensional detection can also be accomplished by combining two or more types of detectors. Thus, reaction rates can be corrected for the influence of temperature and pH during fluorimetric kinetic measurements by simultaneously monitoring fluorescence, pH and temperature.\textsuperscript{18} A block diagram of the equipment used for this purpose is shown in Figure 3.

Long-wavelength fluorogenic reagents are being increasingly used to improve the selectivity of fluorimetric methods by avoiding potential spectral interferences of the sample matrix with analytical measurements, which are often encountered with conventional fluorescence reagents. The combined use of kinetic methodology and these reagents has been shown to boost selectivity through temporal and spectral discrimination of the analytical signal. This approach has been applied to the kinetic determination of proteins such as gliadins\textsuperscript{19} and caseins\textsuperscript{20} in foods, by reaction with a surfactant and suppression of the quenching effect of the surfactant on the fluorescence of the fluorophore. The increase in fluorescence intensity with time is directly related to the protein concentration.

The inception of computers in analytical chemistry has allowed new developments in data processing for kinetic fluorimetric determinations; applications, however, remain scant. For instance, the Kalman filter,\textsuperscript{21} an algorithm for the recursive estimation of the parameters and states of a system from a series of noisy measurements, has been used to determine the parameters for data files with different rate constants, and has been applied to the fluorescent reactions of amino acids with phthalaldehyde.\textsuperscript{22}

![Figure 3](image-url)
Dynamic fluorimetric detection has scarcely been used in combination with separation techniques. Recently, a reaction kinetic model combined with a number of theoretical and experimental variables was developed to evaluate the dynamic ranges and detection limits obtained for biotin as a function of the streptavidin concentration. For this purpose, laser-induced fluorescence detection was used in postcapillary affinity detection for capillary zone electrophoresis.

3.2 Phosphorescence

Kinetic methodology has been used in phosphorimetry mainly to determine the lifetime of the excited triplet state, which is the analytical parameter in time-resolved phosphorimetry as shown in the following section. However, this approach has scarcely been used in analytical applications involving measuring the rate of formation of a phosphorescent system in solution using MSRTTP. Similar to other analytical techniques, this can be done by recording the kinetic curve that reflects the variation of the phosphorescence with time and using its slope as the analytical parameter. This is especially useful when the phosphorescent signal is unstable or takes a long time to stabilize, which is very usual in phosphorescent systems and hinders application of phosphorescence methods to routine analyses. This approach has been applied to the determination of carbaryl in the presence of sodium dodecyl sulfate (SDS) and the thallous ion. The advantages of this determination are noted in section 6.2. The stopped-flow (SF) mixing technique was required to measure the fast initial rate of the system.

The term “kinetic phosphorimetry” was coined in connection with a method for the determination of uranium, based on laser excitation followed by temporal resolution of the phosphorescence signal. As noted in section 2, in the absence of side processes, the equation that describes the first-order kinetic decay of the excited species can be written as Equation (10):

$$\ln I_t = \ln I_0 - (k_p + k_q) t$$

where $I_t$ and $I_0$ are the phosphorescence intensities at time $t$ and 0, respectively, and are proportional to the concentration of the emitting species, $k_p$ is the rate constant for phosphorescent decay, and $k_q$ is the rate constant for all other relaxation processes. The number of detected photons at any time $t$ is proportional to the number of excited species. Thus, a linear fit of the phosphorescence intensity data in the above equation gives an intercept at time $t = 0$, $\ln I_0$, proportional to the number of excited species, irrespective of quenching effects. The luminescence from the analyte is related to its concentration using the intercept $I_0$ from the above expression in the calibration equation obtained with known analyte standards. The decay lifetime, $\tau$, which is the reciprocal of $(k_p + k_q)$, corresponds to the negative reciprocal of the slope in the above equation. As a result, the linear fit of this equation allows the calculation of the concentration of the analyte and its lifetime. The use of a dye laser source is very appropriate for this type of spectroscopic measurement because of its high intensity, monochromatic radiation and the possibility of varying the excitation wavelength. Figure 4 schematically depicts the equipment required.

The determination of uranium by using this methodology is based on the fact that the luminescence decay of an excited uranyl complex follows first-order kinetics, so the intensity of the uranyl luminescence emission declines exponentially after excitation with each laser pulse and the logarithm of the luminescence intensity is a linear function of time. The luminescence intensity at time zero after termination of the laser pulse, the initial luminescence intensity, is proportional to the uranyl concentration. The method has been applied to the determination of uranium in water, urine, milk and soil samples. Analyses of more complex biological samples have been limited because the organic components cause quenching of the luminescence associated with the uranyl ion. Quenching can compete with phosphorescence by shortening the excited-state lifetime and reducing the luminescence intensity, thus affecting the specificity.

Figure 4 Schematic diagram of the kinetic phosphorescence analyzer: (R) reference cell; (S) sample cell; (L) focusing lens; (F) interference filter; (A) apertures to the detectors; (M) mirrors. (Reproduced by permission of the American Chemical Society, from Brina and Miller.)
sensitivity and accuracy of the method. However, analysis of these samples has been accomplished\(^{26}\) by previously heating at 600 °C.

### 3.3 Time-resolved and Phase-resolved Luminescence

As noted in section 2, luminescence lifetimes can be determined by using time-resolved and phase-resolved methods. There is extensive literature about both approaches.\(^{10,11}\) Briefly, in the time-resolved method, the sample is excited with a short-duration pulse of light, and the time-dependent decay of the fluorescence intensity is used to calculate the lifetime. In the phase-resolved method, the sample is excited with sinusoidally modulated light and the phase shift and demodulation of the emission, relative to the incident light, are used to calculate the lifetime. Each method has some advantages and disadvantages. The choice depends on several variables, including the nature of the sample, deviation of decay from ideality, and lifetime range desired.\(^{7}\) However, only the time-resolved method allows the kinetic curve to be obtained. The resolution of spectrally similar fluorophors or phosphors based on differences in lifetime is suitable when instrumental or spectroscopic methods for simultaneous determinations fail, when it may be difficult to separate the components in the sample or when chemical treatment of the sample may increase analysis time or introduce contamination. It is very unlikely that two components will have the same lifetime as well as the same excitation and emission spectra.

The qualifier “time-resolved” has been also applied to a series of determinations involving no luminescence lifetime measurements. These methods are based on the use of chemical systems with relatively long luminescence lifetimes. Equilibrium measurements are obtained in the phosphorescence mode, using preset delay and gating times. Lanthanide chelates, which are the subject of the next section, have been widely used for this purpose. A very interesting analytical application of these chelates is their use as labels in time-resolved fluorescence immunoassays.\(^{27}\)

### 3.4 Lanthanide-sensitized Luminescence

The high coordination number of lanthanide ions allows the formation of luminescent ternary complexes, where one of the ligands absorbs the excitation light and efficiently transfers the energy to the chelated ion, whereas the second ligand has a merely synergistic effect, removing water molecules, which are deleterious to lanthanide emission, from the coordination sphere of the ion. The analytical applications of lanthanide-sensitized luminescence are of great interest\(^{28}\) since lanthanide chelates exhibit a special behavior as a result of the intramolecular energy transfer from the excited triplet state of the ligand to the emitting level of the central ion, which partly or completely circumvents the selectivity restrictions of luminescence methods. Thus, the large Stokes shifts and narrow emission bands of these chelates afford the spectral discrimination of the analytical signal, while their relatively long lifetimes enable temporal discrimination from analytical measurements made in the phosphorescence mode to avoid scatter, Raman and any fluorescence background signals. In addition, this time-resolved mode increases the analytical signal, as this is integrated over a longer period than in the fluorescence mode, which results in improved detection limits.\(^{29,30}\)

This luminescence process can be considered a special type of sensitized phosphorescence. One difference between the use of lanthanide ions as energy acceptors instead of compounds such as biacetyl or 1,4-dibromonaphthalene is that, with the latter, the energy transfer is intermolecular; this accounts for the low efficiency relative to the former, which involves intramolecular energy transfer. One other difference of practical interest is that no oxygen removal is required. The most efficient energy acceptors among lanthanide ions are terbium(III) and europium(III), which form stable complexes with many organic compounds.\(^{28}\)

Although the formation of lanthanide chelates is generally very fast and the luminescence signal rapidly stabilizes, it has been shown that the use of initial rate measurements instead of equilibrium measurements can improve the selectivity of a determination.\(^{31}\) Figure 5

![Figure 5](image-url)
shows the kinetic curves obtained for the terbium(III)-propyl gallate system in the presence of other gallate derivatives. As can be seen, the equilibrium signal is modified by these compounds, while the initial slope of the kinetic curves is unaffected. The usually high formation rate of lanthanide chelates precludes the use of the batch technique and justifies the use of the SF mixing technique, which, in addition, minimizes reactant manipulation and ensures a high throughput, as shown in section 6.2.

4 CHEMILUMINESCENCE

The CL process is probably the most markedly kinetic of the luminescent phenomena as the factors that affect the emission intensity are a combination of luminescence and chemical reaction rate aspects (see section 2). Thus, taking into account that CL measurements are dynamic in nature, because they are based on the detection of a transient light emission, all CL methods might be classified as kinetic methods. A large number of methods based on CL reactions have been reported in the last few years.

The analytical parameters most frequently employed in CL methods are the peak intensity and the integrated area under all or part of the light emission–time curve. In both instances, one must rigorously control the interval between initiation of the reaction and acquisition of data. However, formation and decay rates of CL reactions have been found to provide better precision and selectivity that conventional parameters, which, as shown in section 6.2, have been obtained by using SF mixing technique. This section describes some general aspects about the analytical interest of the different CL processes, namely conventional CL, electrochemiluminescence and BL.

4.1 Conventional Chemiluminescence

The reactions used in CL methods can be direct or indirect, depending on the origin of the CL. They involve the processes represented by Equations (11–14):

\[
A + B \rightarrow C^* \quad (11)
\]

\[
C^* \rightarrow C + \text{light} \quad (12)
\]

and

\[
C^* + D \rightarrow C + D^* \quad (13)
\]

\[
D^* \rightarrow D + \text{light} \quad (14)
\]

In the former case, the reaction produces the primary excited-state molecule, which is responsible for the subsequent light emission; in the latter process, known as a “sensitized reaction”, the excited product is not the light emitter, but rather transfers its energy to a fluorescent acceptor, which then emits light. The use of sensitized CL has distinct advantages in the design of analytical systems, as optimum structural features can be designed and incorporated into separate chemical reactant and fluorophore molecules. The fluorophore is selected to provide the optimum compromise between excitation and emission wavelengths, chemical stability and quantum yield. This is in contrast to direct CL, where reactivity and fluorescence properties reside in a single molecule. Extensive literature on the different types of CL systems is available.

The duration of CL reactions varies from very short (<1s) to very long (>1 day). In any case, because the signal is transient, measurements of CL intensity are time-dependent, which dictates the choice of method for mixing the reactants. Batch luminometers are based on static systems where the sample is placed in a cuvette that is accommodated in the instrument and the CL reagent is added either manually (with a syringe) or via an automatic injector. The CL intensity is usually monitored over a preset time interval. This approach can be used when the CL reaction has a long lifetime, but it is unsuitable for reproducible monitoring of a fast CL reaction (<15s). In the latter case, the use of flow systems allows the reactants to be mixed rapidly and reproducibly in front of the detector, as shown in section 6. The combination of CL detection and liquid chromatography (LC) is particularly attractive, but the sensitivity of CL detection and the selectivity of LC must be balanced against the incompatibility of the best mobile phase for separation and the best conditions for the CL reaction.

4.2 Electrogenerated Luminescence

Electrogenerated chemiluminescence (ECL), also known as “electroluminescence” or “electrochemiluminescence”, is a process by which electrochemically generated reactants undergo high-energy electron transfer reactions in solution, to yield excited-state molecules. Usually, cation and anion radicals are produced from electron donor and acceptor molecules at an electrode surface, which is achieved by applying double step potentials to the electrode to give positive and negative potentials respectively. The radical species produced then undergo an electron transfer reaction to give the excited state of either or both reactants. Thus, the CL reaction takes place in the vicinity of an electrode and involves electrochemically generated active species. This technique retains the advantageous sensitivity and selectivity of conventional CL and affords greater control over the initiation, rate and course of the reaction, as this is produced by electrical stimulation. It provides a direct monitor of reaction rate, as the photon flux is proportional
to the rate of the oxidation or reduction that produces the excited species.

Although the ECL process has been studied for many years, it has only recently emerged as a useful tool for the determination of a variety of analytes.\(^{(36)}\) The earliest research in this direction was aimed at studying the nature of the emitting state, the mechanisms by which it is produced and the efficiency with which the excited state is generated. Available methods are usually implemented in static electrochemical systems that are modified to include the optical measurement system, allow the reactants to be generated in situ and facilitate dismantling for cleaning. However, ECL detection systems for the flow injection (FI) and liquid chromatographic techniques have also been reported, as has the immobilization of ECL reagents to develop sensors and probes.\(^{(36)}\)

The full potential of analytical ECL has not yet been realized, and further work is needed to overcome the problems posed by electrode fouling, to increase the stability and robustness of immobilized ECL reagents, and to improve flow cell designs, which are complicated by the incorporation of electrodes and an optical measurement device.

### 4.3 Bioluminescence

Bioluminescence is a type of CL in which visible radiation is emitted from living organisms or systems derived therefrom. BL reactions involve luciferase-catalyzed oxidation of luciferins, where luciferase is the enzyme and luciferin the substrate. The systems most widely used for analytical purposes involve firefly and bacterial luciferase.\(^{(33)}\) The high sensitivity associated with BL detection has been exploited in the design of analytical methods with excellent detection limits. The basic kinetics of BL analysis, use of coupled enzyme reactions with a final luminescence step, amplification of luminescent reactions by enzymatic cycling and the use of BL in the assay of enzyme activity have been discussed.\(^{(37,38)}\)

One recent application of kinetic methodology to BL analysis is the automatic determination of urea by using ATP-hydrolyzing urease, firefly luciferase and luciferin.\(^{(39)}\) Light intensity was measured at 40 and 80 s after addition of the urease reagent. Also, a kinetic assay of glycerol for lipolysis studies was developed\(^{(40)}\) by using photinus-luciferin 4-monoxygenase, luciferin and glycerol kinase. BL intensity was measured every 0.2 min for 1.2 min.

### 5 IMMUNOASSAY

Different luminescence techniques have been applied to the determination of species by using immunochemical reactions that have given rise to a number of homogeneous and heterogeneous immunoassays. Homogeneous immunoassay is known to be simpler and faster than heterogeneous immunoassay as it involves none of the incubation, separation and wash steps of the latter, but detection limits are generally higher, mainly as a result of the sample matrix background.

Many homogeneous immunoassays involving fluorimetric detection use fluorescein (\(\lambda_{\text{ex}}\) 492 nm, \(\lambda_{\text{em}}\) 517 nm) as a label. This compound has a narrow Stokes’ shift, which can pose light-scattering problems; also, its fluorescence emission can be compromised with the background fluorescence from the sample matrix. However, this problem can be overcome by using fluorophores such as oxazines, thiazines or cyanines, which give emission bands more red-shifted than that of fluorescein, and measuring the initial rate of the immunochemical reaction in order to accomplish spectral and temporal discrimination, respectively, of the analytical signal as an alternative to the physical separation required in heterogeneous immunoassay. These compounds also exhibit a short fluorescence lifetime, which decreases the likelihood of nonradiative quenching processes. Despite their potential, the utility of these compounds as hapten labels in immunoassay has scarcely been studied because the covalent labeling efficiency of oxazine and thiazine dyes with carboxylic acid-containing analytes is low. However, the efficiency can be improved by using a bifunctional reagent such as a carbodiimide derivative. The combined use of kinetic methodology and an oxazine label, namely Cresyl Violet, has enabled the determination of 2,4,5-trichlorophenoxyacetic acid, a herbicide used to control shrubs and trees, in liquid food samples.\(^{(41)}\) The high initial rate of the immunochemical reaction was measured by using the SF mixing technique.

One other homogeneous technique is fluorescence polarization immunoassay (FPIA), which is a competitive binding assay where the tracer (the antigen conjugate) binding with the antibody is directly measured without the need for a separation procedure. It relies on the fact that, when a molecule is excited by polarized light, the emitted light will also be polarized, provided the molecule does not rotate during the time elapsed between excitation and emission. Small fluorescent molecules rotate rapidly, and normally exhibit no fluorescence polarization; on binding to macromolecules, however, the rotation motion is slowed down and the fluorescence remains polarized. Thus, the tracer, which competes with the analyte for the antibody, will only exhibit polarized fluorescence (which will be inversely proportional to the analyte concentration) when bound to the antibody.

Fluorescence polarization is usually expressed as the degree of polarization \(P\) (Equation 15):
where $A$ and $B$ are the fluorescence intensities measured with the emission polarizer parallel and perpendicular, respectively, to the excitation polarizer. A variety of electronic and optical assemblies have been used\(^{(42)}\) to perform fluorescence polarization measurements. Conventional FPIA involves measuring $P$ when the formation of the tracer–antibody complex has reached or is close to equilibrium. However, measuring the variation of $P$ with time ($dP/dt$) allows one to obtain the reaction rate of the tracer–antibody complex, which is inversely proportional to the analyte concentration. Kinetic methodology avoids or minimizes the static signal from the sample matrix, which is usually the main cause of the relatively high detection limits afforded by conventional FPIA. This has been demonstrated in the determination of therapeutic\(^{(43)}\) and abuse\(^{(44)}\) drugs, and also of atrazine.\(^{(45)}\) Table 1 compares the detection limits obtained for some of these compounds by using equilibrium and kinetic measurements in FPIA.

The only requirement for application of kinetic methodology in FPIA is the availability of instrumentation enabling simultaneous measurements of the variation of $A$ and $B$ with time to be processed by a microcomputer in order to construct a polarization–time kinetic curve. A T-format spectrofluorimeter with two emission channels symmetrically arranged on both sides of the sample compartment and with the emission polarizers placed perpendicular to each other is a suitable choice (Figure 6). Conventional kinetic measurements (batch technique) are unsuitable in FPIA because the initial rate of the competitive antigen–antibody reaction is usually very high, but it can be obtained by using the SF mixing technique.

Both homogeneous and heterogeneous immunoassays have been developed using CL detection. Similarly to other immunoassay techniques, the CL homogeneous format is technically more simple, but it is subject to problems arising from endogenous background interference, which are avoided in the CL heterogeneous format. As in other CL methods, the analyte concentration is usually related to the maximum emission intensity or the integrated light output over a fixed fraction of the total reaction time, although it has also been reported that the precision can be improved by measuring the rate of intensity change over a wide interval after mixing.\(^{(46)}\)

A variety of reactions have been evaluated and shown to be suitable for use in CL immunoassay. Indeed, hundreds of reports describing such reactions have appeared in the literature.\(^{(47–49)}\) CL immunoassays can be classified into three groups, as follows.

1. Those where the label can be a CL or BL substance, such as luminol or the enzyme luciferase. Typical problems with them include a considerable loss of CL efficiency and enzyme activity, respectively, on linking to other molecules such as antigens or antibodies.

2. Those where the label can be a catalyst or a cofactor for a CL reaction. One case in point is peroxidase, which is a catalyst for the luminol–peroxide reaction, and nicotinamide adenine dinucleotide (NAD), which is a cofactor for the BL reaction catalyzed by bacterial luciferase–oxidoreductase.

6 AUTOMATION

Similarly to other kinetic determinations, automation has played a crucial role in luminescence-based kinetic determinations by facilitating application to routine analyses. For instance, automatic luminometers for BL determinations are now commercially available and can measure the maximum intensity or integrate the light output over a selection of fixed times. Some such luminometers have been specifically designed for measurement of ATP or nicotinamide adenine dinucleotide phosphate (reduced form) (NAD(P)H). This section briefly reviews the different automatic kinetic approaches based on luminescence detection, namely FI, SF and continuous addition of reagent (CAR). Applications of these methods to drug analysis were recently reviewed.

6.1 Flow Injection

Flow injection has proved extremely useful for luminescence-based kinetic determinations. The automated sample handling, controlled sample dispersion and precise time aspects of this approach are distinct advantages. Among FI modes, SF FI and sequential injection are specially useful for kinetic-based determinations. In the SF FI mode, after a preset delay time, the pump is stopped and then re-started after the SF period has elapsed. This allows a selected portion of the dispersed sample zone to be arrested in the observation field of the detector. As physical dispersion virtually ceases when the carrier stream is stopped, the variation of the signal with time reflects the kinetics of the chemical reactions between the mutually dispersed components of the injected sample and carrier stream. This approach allows the reaction rate to be measured as it is not affected by the static background signal from the sample. Figure 7 shows a schematic diagram of the system (a), a portion of the dispersed sample zone (b) and the variation of the signal with time at three different analyte concentrations (c). The system is furnished with a timer (T) that is started when valve S is switched to its injection position. The SF FI mode differs from the normal SF technique, which is described in the next section, in that (a) sample and reagent are not mixed at a high pressure, (b) the former does not allow fast reactions to be monitored and (c) real-time analyses (e.g. in an enzymatic reaction) are more difficult to accomplish because of the continuous nature of the flow. An attempt at overcoming the pitfalls of this technique was made by developing an automated micro SF continuous apparatus for serial measurements on enzyme reactions. It uses two symmetrically arranged sets of sample injectors (FI system) and stops the carrier stream (SF system), which circulates at a high flow-rate, by means of a high-speed peristaltic pump. Equipped with suitable detectors, the apparatus was used as a real-time analyser for column chromatography.

Sequential injection is a second-generation SF technique based on the sequential aspiration of sample and reagent zones through a selector valve into a holding
coil, as shown in Figure 8. A stack of well-defined zones is thus obtained. The flow direction is then reversed, and the zones are injected into a reactor and detector. The flow reversal creates a composite zone in which sample and reagent zones penetrate each other. For kinetic determinations, the flow is then stopped and a portion of the composite zone is trapped inside the flow cell of the detector, which allows measurement of the reaction rate.

A procedure for obtaining kinetic data from FI peak profiles by correcting for the effects of dispersion was developed by Chung and Ingle. The method acquires and stores the peak profiles of a nonreacting reference solution and a reacting sample solution. The dispersion coefficients obtained from the reference profile are used to normalize the profile of the sample solution. The utility of this method was demonstrated by adapting a kinetic fluorimetric method for the determination of aluminum with acid alizarin garnet R and using the fixed-time method.

As noted in section 4.1, the shortcomings of batch luminometers can be circumvented by using FI systems. FI CL methods are simplified by reducing the number of reagents that need to be pumped separately to the reaction site, as reagents can be electrochemically produced from passive precursors in the carrier medium. A typical instrumental set-up that was applied to morphine determination is shown in Figure 9. The sample is injected into one flowing stream and the CL reagent flows in the other stream. The two streams meet head-on at a T-piece, inside a light-tight casing, and then flow through a flat coil placed immediately in front of the detector. The coil serves to retain the solution in view of the detector whilst it is emitting most intensely. The system provides very rapid, reproducible mixing and emission intensities, and affords a high throughput.

One other choice in CL analysis is the use of immobilized systems. In this case, the CL intensity depends on both the kinetics of the CL reaction and on the efficiency of mass transfer processes involved in bringing the reactants into contact. Similarly to the use of enzymes, the principal advantages of BL reagents (e.g. firefly or bacterial luciferase) immobilized on solid supports are their reusability, which can significantly reduce reagent costs and improve stability, sensitivity and compatibility with automated continuous flow analyzers. The use of ECL as detection system for LC and FI has given rise to the development of various types of ECL flow cells.

6.2 Stopped-flow

The SF mixing technique is the automatic approach based on kinetic methodology most commonly used when fast reactions are involved. In applying this technique,
two reactants are driven at a high speed by means of two drive syringes through a mixing chamber, the flow of the reactants being abruptly stopped by using a third, stop syringe, and the extent of reaction being monitored by measuring a given property such as the luminescence emission. The most salient features of the SF technique are its ability to mix sample and reagent solutions automatically, the possibility of making measurements shortly after mixing, a high overall precision and minimization of potential interferences. Although this technique is specially suitable for fast reactions (it facilitates the study of the kinetics and mechanisms of these reactions and their use in developing kinetic determination methods), it has also proved useful for developing quantitative methods involving slower reactions as it minimizes reactant manipulation and affords a higher precision than do conventional kinetic approaches. These features make the SF technique particularly attractive to routine laboratories, which require automated instrumentation, high throughputs and the ability to use low solution volumes.\(^\text{(61)}\)

The SF approach shows attractive features when applied to CL monitoring. Thus, mixing is very rapid, the emitting solution may be retained in the measuring cell for whatever time is desired and, unlike the FI approach, the intensity–time curve can be monitored, thus allowing kinetic measurements to be made (see Figure 10). Formation and decay rates of CL have been found to provide better precision and selectivity than conventional parameters such as the peak high intensity or the area under the emission light–time curve.\(^\text{(32)}\) This approach was tested for the first time on the determination of hydrogen peroxide by its classical reaction with luminol catalyzed by cobalt,\(^\text{(32)}\) and has proved useful for other determinations such as penicillins\(^\text{(62)}\) and manganese.\(^\text{(63)}\)

The SF mixing technique in combination with MSRTP was demonstrated by developing a kinetic method for carbaryl determination.\(^\text{(24)}\) Compared with conventional MSRTP, where a phosphorescent system takes a relatively long time to reach equilibrium, the special features of the SF mixing technique allow the fast acquisition of kinetic data and provide a very simple means of accomplishing automation in phosphorescence routine analyses. This approach also avoids the two major constraints of solid-surface room-temperature phosphorimetry (SSRTP), namely the presence of a background signal from the solid supports used, which affects detection limits, and the critical preparation and measurement requirements, which influence the precision of the analytical results.

The term “SF-fluoroimmunoassay” has been applied to the use of this mixing technique in homogeneous determinations based on immunochemical reactions. This approach was used for the determination of the pesticide 2,4-dichlorophenoxyacetic acid in fruit juice samples.\(^\text{(64)}\) The system was characterized by the very fast initial rate of the antigen–antibody reaction and the fluorescence quenching of the tracer (fluorescein-labeled pesticide) upon reaction with the antibody. The signal obtained at equilibrium was severely affected by the presence of the sample matrix, which is very common in fluorescence quenching methods, since the static signal is highly sensitive to the environmental conditions. This shortcoming, however, was avoided by measuring the initial rate of the system. SF-immunoassay was also applied to the development of a direct homogeneous method for the determination of coproporphyrin\(^\text{(65)}\) in urine, based on the native fluorescence of this porphyrin and the use of the initial rate of the antigen–antibody reaction as analytical parameter, which was obtained by measuring the decrease in fluorescence intensity with time. The method is simpler than the competitive immunoassay, where a tracer is used, and avoids the separation step required in heterogeneous immunoassay.

### Figure 10

6.3 Continuous Addition of Reagent

The CAR technique is a fairly recently reported open system approach based on the continuous addition of a reagent solution, at a constant rate, to another solution containing the species to be determined.\(^\text{(66)}\) Analytical data obtained from second-order reactions are processed by using a mathematical treatment that relates kinetic parameters with the experimental variables. This treatment also allows the second-order rate constant of the system to be determined. The chief advantages of this technique are that the kinetic response curve can be readily obtained from both slow and fast reactions (for which the first-order condition is commonly used).
with straightforward instrumentation since the reaction is made second-order.\(^{67}\) The typical instrumental set-up consists of: (1) an addition unit with an autoburette, a magnetic stirrer and a thermostated vessel (the reaction cell); (2) a detection system such as a luminescence detector; and (3) a computer unit for data acquisition and processing. The second-order kinetic profile of the signal versus time (or volume added) response includes a straight portion, the slope of which is proportional to the analyte concentration (maximum-rate method); this is equivalent to the initial-rate method used for pseudo first-order kinetic responses in the SF technique.

The CAR technique has been applied to the fluorimetric determination of morphine in urine\(^{68}\) using the classical oxidative dimerization of this drug by alkaline potassium hexacyanoferrate(III) to form a highly fluorescent dimer (pseudomorphine). The conventional method poses problems arising from instability of the reaction products and undesirable interactions between them and the excess of reagent, which quench the fluorescence of pseudomorphine. However, the CAR technique avoids these problems since the reagent is continuously added from the autoburette, thereby increasing the fluorescence intensity.

The adaptation of the CAR technique to CL reactions has allowed some problems of the analytical application of these reactions to be solved. Thus, this approach is an effective means for suppressing background emission in peroxyoxalate CL reactions, which is ascribed to the formation and decomposition of CL reaction intermediates. This ability arises from the special way in which the sample and reagent are mixed in the CAR technique, in addition to its kinetic connotations. The analytical utility of the combination of the CAR technique with CL reactions has been demonstrated by applying the bis(2,4,6-trichlorophenyl)oxalate (TCPO)/hydrogen peroxide system to the determination of acepromazine in horse plasma samples.\(^{69}\) The CAR technique has also been used as an effective means for enhancing the performance of energy transfer CL-based determinations involving the use of a sensitizer. Thus, the reaction between tertiary aliphatic amines and sodium hypochlorite in an alkaline medium containing fluorescein as sensitizer has been used to determine trimethylamine in fish samples.\(^{70}\)

### 7 SIMULTANEOUS DETERMINATIONS

Although classical differential kinetic methods have been applied in simultaneous determinations with luminescent detection, recent investigations have chiefly been aimed at accomplishing mathematical discrimination by using complex chemometric methods or instrumental discrimination by use of multidetection devices. Procedures that exploit both kinetic and spectral differences have thus been developed. Also, automation is a general trend in the latest simultaneous determinations.

Among classical approaches, the proportional-equation method has been applied in conjunction with the SF mixing technique to the simultaneous determination of salicylic acid and diflunisal\(^{30}\) by the combined use of kinetic and equilibrium measurements. The similar structures of these compounds result in mutual interferences with the determination of each other. Thus, the corresponding ternary anionic chelates formed with terbium(III) and ethylenediaminetetraacetic acid (EDTA) in an alkaline medium exhibit the same initial rate and equilibrium luminescence intensity. However, the presence of cetyltrimethylammonium bromide (CTAB) increases both parameters to a different extent, which has been ascribed to the formation of ion-association complexes between CTAB and the ternary anionic chelates formed by salicylate and diflunisal with terbium(III) and EDTA in the alkaline medium. Epinephrine and norepinephrine were simultaneously determined in urine\(^{71}\) by using the trihydroxyindole method, which was simplified by implementing the SF technique.

Micellar media provide additional advantages that have scarcely been explored in simultaneous kinetic analyses with luminescence detection. Micelles can alter the apparent rate constant of two or more species with similar structure, interacting with a common reagent by both altering their intrinsic reactivity and, more generally, binding to a different extent to analytes. This effect has been applied to the simultaneous determination of pyridoxal and pyridoxal-5'-phosphate by using their cyanide-catalyzed oxidation in the presence of CTAB micelles.\(^{72}\) The initial rate and the fluorescence intensity increment of these systems were used as analytical parameters and data were processed by using a system of two equations which was solved by multiple linear regression.

The logarithmic extrapolation method was applied to the simultaneous determination of thiamine and its pyrophosphate ester, cocarboxylase,\(^{73}\) using the differential oxidation rate of these compounds with mercury(II).

The T-format spectrofluorimeter described above, furnished with an SF module, was used for the direct resolution of a mixture of two drugs, neomycin and promethazine (an antimicrobial and an antihistamine respectively), which are found together in some pharmaceutical preparations.\(^{74}\) This was the first reported application of kinetic methodology based on reaction-rate measurements to a simultaneous fluorimetric determination using a dual-channel instrument. As the T-format configuration has two emission paths symmetrically...
LUMINESCEENCE-BASED KINETIC DETERMINATIONS

arranged on both sides of the sample compartment, it allows one to simultaneously monitor the development of the reaction of neomycin with α-phthalaldehyde in the presence of N-acetylcyesteine and the oxidation of promethazine by dissolved oxygen without the need for an oxidant such as hydrogen peroxide, since both reaction products have similar excitation wavelengths but different emission wavelengths. The absence of overlap in the emission maxima allows one to obtain kinetic data from each individual system, even if both possess similar rate constants and their reactions are fast. In this instance, both systems exhibited a disparate kinetic behavior: whereas neomycin reached equilibrium within only 3–4 s, promethazine took about 40 s. However, their high initial rates justified the use of the SF mixing technique. The method allowed the resolution of mixtures containing neomycin and promethazine in ratios between 8:1 and 1:9, and was applied to pharmaceutical analyses.

This approach was also applied to the simultaneous determination of the antibiotics ampicillin and tetracycline in milk. The determination of ampicillin was based on its hydrolysis with penicillinase and reaction with mercuric chloride; that of tetracycline relied on the intramolecular energy transfer from the analyte to europium ions in the presence of thenoyltrifluoracetone. Owing to the differential kinetic behaviour of the two chemical systems involved, kinetic and equilibrium measurements were carried out to obtain quantitative data for penicillin and tetracycline, respectively.

The flexibility and simplicity of the FI approach has been exploited in the development of a number of differential kinetic methods. Thus, the differential catalytic activity of manganese(II) and iron(III) ions on the oxidation of salicylaldehyde thiosemicarbazone by hydrogen peroxide has been used for the simultaneous determination of these ions with an FI configuration that splits the sample into two channels with different geometric and hydrodynamic characteristics and then recombines both channels prior to the detector. The differential residence times for the sample portions result in two peaks in which the contribution of each ion to the formation of the oxidation product is different.

Regarding chemometric methods, the Kalman filtering algorithm has been applied to the simultaneous time-resolved determination of antibiotics such as tetracyclines and anthracyclines in solution by formation of luminescent chelates with europium(III). An optosensing FI manifold involving a flow cell packed with a nonionic resin was used in both instances. Each determination utilized the differences in decay rates of the chelates adsorbed onto the resin and the Kalman filter to process decay data.

Artificial neural networks have been used in combination with the CAR technique to resolve phenothiazine mixtures by using CL reactions with a peroxyoxalate derivative. The CAR technique suppresses background emission from these CL reactions. The chemometric method allows the simultaneous determination of trimiprazine and methotrimeprazine, even though both compounds exhibited a similar kinetic behavior and synergism. Luminol CL induced by hexacyanoferrate(III) and enhanced by phenolic acids was used for the simultaneous determination of procatechuc and caffeic acids. The synergistic effects present required the use of surface response and least-squares matrix methodologies.

Kinetic fluorescence detection has been utilized for the determination of glycine and glutamine (previously partially separated on a thin-layer chromatography (TLC) plate). The formation and decay of the intermediate fluorescent products formed between these species and α-phthalaldehyde was monitored with a charged-coupled device camera by taking sequential images of the TLC plate. A direct trilinear decomposition method was used to analyze the resulting third-order data, which consisted of fluorescence intensities as a function of elution distance, reaction time and sample number.

8 FINAL REMARKS

The analytical interest of luminescence-based kinetic
determinations is the result of the high sensitivity and
versatility of luminescence techniques together with the
temporal discrimination of the analytical signal that is
obtained by using kinetic methodology. Table 2 summa-
rizes some selected examples of these determinations,
which shows the wide application field of this approach.

Analytical procedures in which the measurement step (chemical, physical or physicochemical) is influenced by a transient (kinetic) process, can strictly be classified as kinetic method. Thus, the majority of modern analytical methods (continuous-flow, time-resolved fluorimetric and chromatographic methods, among others) are kinetic in nature. Nevertheless, the term “kinetic method”, for historical reasons, is incorrectly limited to methods based on direct or indirect measurements of the rate of a chemical reaction, which should be classified as “reaction-rate methods”. Analytical methods based on signal measurements made under dynamic conditions compete in efficiency with static and equilibrium measurements. The growing development of kinetic methods is due to the need for quantification of microamounts of substances, increasing knowledge of reaction mechanisms, and breakthroughs in instrumentation and data handling and interpretation. The most popular classification of kinetic methods of analysis is based on the chemistry of reactions employed and distinguishes between catalytic (nonenzymatic, enzymatic and electrochemical), and noncatalytic methods. The latter are further categorized into those used to determine a single species or several components in mixtures (differential reaction-rate methods). This article deals with kinetic methods for the determination of single noncatalytic species. Although the majority of kinetic-based determinations depend on catalytic systems, some analytical applications using the rate of uncatalyzed reactions are of analytical interest, mainly those involving organic chemical species. Advances in instrumentation: (1) improved signal detection, (2) resolving of problems arising from time measurements especially in fast processes, and (3) availability of automated mixing devices and data processing (error-compensated methods, curve-fitting and predictive approaches) establish noncatalytic methods as powerful alternatives to equilibrium methods. The main field of application of noncatalytic reactions is organic analysis, unlike catalytic reactions where a metal ion usually acts as the catalyst.

1 THEORETICAL BACKGROUND

1.1 Reaction Rate and Kinetic Equation

The kinetic determination of a noncatalytic species is based on the monitoring of its reaction rate by direct or indirect measurements of changes in the reactant or product concentration. The reaction rate is defined as the change in concentration of one of the components (reactant consumed or product formed) of the chemical system per unit time. From a practical analytical viewpoint, methods using uncatalyzed reaction rates are limited to those following pseudo-zero-order, first-order, and pseudo-first-order kinetics, since most of the chemical systems used involve bimolecular reactions and orders higher than two are rare and of no analytical applicability.

For a straightforward reaction of the type \( A + R \rightarrow P \), where \( A \) is the species of analytical interest (analyte), \( R \) is the added reagent and \( P \) is the product, the general
The pertinent kinetic equation can be derived as Equation (2)

\[ \text{rate} = \frac{d[P]}{dt} = -\frac{d[A]}{dt} = -\frac{d[R]}{dt} \]  

(1)

in which the derivatives of [A] and [R] are negative because both species are consumed as the reaction proceeds. The reaction rate at time \( t \) depends on the concentrations of all the species involved and the pertinent kinetic equation can be derived as Equation (2)

\[ \text{rate} = \frac{d[P]}{dt} = k[A][R] \]  

(2)

where \( k \) is defined as the rate constant and expresses the reaction rate per unit concentration of the reactants. The reaction order is defined as the sum of the exponents of [A] and [R] in Equation (2), known as partial reaction orders; thus, the above reaction is second order.

In the case of one of the reactants (e.g. R) being present in a large excess (over 50-fold) relative to the other, then its concentration remains practically constant and can be included in the term \( k \) in Equation (2) and the reaction is considered to be pseudo-first-order in A or pseudo-zero-order in R, i.e. Equation (3)

\[ \text{rate} = \frac{d[P]}{dt} = k_A[A] \]  

(3)

where \( k_A \) is the pseudo-first-order rate constant. The experimental parameters for most kinetic methods are adjusted so that pseudo-first-order reaction conditions are established.

Instead of the concentrations in Equation (1) any measurable quantity of analytical signal (S) directly proportional to concentration (absorbance, fluorescence, etc.) can be used. Special equations are derived when the signal is not linearly related to the concentration (e.g. potentiometric measurements). The changes in reactant or product concentrations as a function of time can be monitored physically or chemically. Physicochemical techniques (spectrophotometry, fluorimetry, potentiometry, etc.) are preferable for reaction monitoring and provide a signal versus time curve. In the majority of kinetic methods only the initial section of the curve is used, i.e. when the reaction has only proceeded by 1–3%. This section is usually linear with a slope proportional to the analyte concentration (initial-rate approach).

1.2 Determination of Reaction Orders and Rate Constants

The kinetic study of a reaction is performed using the so-called **continuous** (in situ) or **discontinuous** (batch) approach. In a continuous kinetic study, an analytical parameter (signal) (absorbance, potential, fluorescence, etc.) related to the changing concentration of a reactant or product is continuously monitored by means of an analytical instrument connected to a recorder, printer or microcomputer. In contrast, in a discontinuous study (usually used for rather slow reactions and processes), aliquots of the reacting mixture are removed by the analyst at pre-selected time intervals and analyzed immediately or all together in a batch mode after quenching (killing) the reaction at the time of sampling. The analytical parameter – time curves can be used for the determination of reaction orders and rate constants, usually after transformation to concentration – time curves.

1.2.1 Determination of Reaction Order

The order of a reaction (or process) may be determined by the following methods.

1.2.1.1 Substitution Method The concentration data obtained in a kinetic study are substituted in the integrated form of the equations that describe the various reaction orders and the \( k \) values are calculated. The reaction is considered to be of that order that follows the reaction orders and rate constants, usually after transformation to concentration – time curves.

A reaction order of 0 gives an integrated rate equation:

\[ x = kt \]

and a half-life equation:

\[ t_{1/2} = \frac{\alpha}{2k} \]

A reaction order of 1 gives an integrated rate equation:

\[ \log \left( \frac{\alpha}{\alpha - x} \right) = \frac{k}{2.303} t \]

and a half-life equation:

\[ t_{1/2} = \frac{0.693}{k} \]

A reaction order of 2 for \([2A \longrightarrow P]\) or \([A + B \longrightarrow P]\) with equal concentrations gives an integrated rate equation:

\[ \frac{x}{\alpha(\alpha - x)} = kt \]

and a half-life equation:

\[ t_{1/2} = \frac{1}{ak} \]

A reaction order of 2 for \([A + B \longrightarrow P]\) with unequal concentrations gives an integrated rate equation:

\[ \log \left( \frac{\beta(\beta - x)}{\alpha(\beta - x)} \right) = \frac{(\alpha - \beta)k}{2.303} t \]
where \( \alpha \) and \( \beta \) are the initial concentrations of reactants \( A \) and \( B \), respectively, and \( x \) is the concentration of each species reacting in a time \( t \).

1.2.1.2 Fitting (Graphical) Method  
Plots of a function of concentration \( C \) of the reactant versus \( t \) can also be used to ascertain the reaction order. Thus, if a plot of \( C \) versus \( t \) results in a straight line, the reaction is zero order. The reaction is first order if the plot of \( \log C \) versus \( t \) yields a straight line and it is second-order if a plot of \( 1/C \) versus \( t \) results in a straight line (in the case of equal initial concentrations).

1.2.1.3 Half-life Method  
As shown above, the half-life is proportional to the quantity \( 1/(\alpha^{n-1}) \), in which \( n \) is the order of the reaction (for a second-order reaction we assume that \( \alpha = \beta \)). Thus, if the same reaction is run at different initial concentrations, \( \alpha_1 \) and \( \alpha_2 \), the half-lives \( t_{1/2(1)} \) and \( t_{1/2(2)} \) are related according to Equation (4)

\[
\frac{t_{1/2(1)}}{t_{1/2(2)}} = \frac{\alpha_2}{\alpha_1}^{n-1}
\]

By taking the logarithms and rearranging we have Equation (5)

\[
n = \frac{\log[t_{1/2(1)}/t_{1/2(2)}]}{\log(\alpha_2/\alpha_1)} + 1
\]

The half-lives are obtained by plotting \( C \) versus \( t \) at two different initial concentrations and reading the time at \( \alpha_1/2 \) and \( \alpha_2/2 \). By substituting these values and the initial concentrations in Equation (5), the order \( n \) is obtained directly. Alternatively, two concentrations during a single run may be taken as \( \alpha_1 \) and \( \alpha_2 \) and the half-lives determined in terms of \( \alpha_1 \) and \( \alpha_2 \).

1.2.1.4 Initial Reaction Rate (van’t Hoff) Method  
In the previous methods 1–3 (sections 1.2.1.1–1.2.1.3), the reaction must be completed to a large extent. The so-called initial reaction-rate method consists of measuring the initial reaction rates \( v_0 \) for different initial concentrations of a reactant, while the initial concentrations of the other reactants are held constant. From Equation (6)

\[
v = rate = \frac{d[P]}{dt} = k[A]^\alpha[B]^\beta[C]^\gamma
\]

it is concluded (since \( B \) and \( C \) are constant) that Equation (7) follows

\[
\log v_0 = \log(d[P]/dt)_0 = constant + a \log [A]_0
\]

The partial reaction order \( a \), with respect to \( A \), is obtained from the slope of the plot of the logarithms of initial rates versus the logarithms of the initial concentrations. In a similar way the partial reaction orders with respect to \( B \) and \( C \) can be determined by two further sets of kinetic runs.

1.2.2 Determination of Rate Constants  
Once the order of the reaction has been determined, calculation of the rate constant can easily be achieved using the above integrated equations by substitution or least squares regression plotting. In the above initial reaction rate method, the antilogarithm of the constant term of Equation (7), which is referred to as the apparent or observed rate constant, \( k_{obs} \), is equal to \( k[B]_0^\beta[C]_0^\gamma \) (Equation 6). Thus, the value of \( k \) is easily calculated from \( k_{obs} \) values using the known initial concentrations of \( B \) and \( C \), and the already estimated partial orders \( \beta \) and \( \gamma \).

Since the majority of the analytical reactions used in kinetic analysis are first- or pseudo-first-order, two commonly used methods for the determination of first-order reaction rate constants from experimental (signal) data are presented.

1.2.2.1 Infinite-time Method  
The course of the reaction is followed by measuring some signal \( S \), which is linearly related to the concentration of one of the reactants or the product. The signal varies with time according to Equation (8)

\[
(S_\infty - S) = (S_\infty - S_0)e^{-kt}
\]

in which \( S_0, S, \) and \( S_\infty \) are the values of the measured signal at \( t = 0, t, \) and \( t = \infty \), respectively. It is obvious that a plot of \( \ln[(S_\infty - S)/(S_\infty - S_0)] \) versus \( t \) will be a straight line with a slope equal to \(-k\) (or \(-k_{obs}\)). This method requires the completion of the reaction.

1.2.2.2 Guggenheim Method  
This method does not require completion of the reaction. If the readings of the analytical signal, \( S_1, S_2, \ldots, S_n \) are made at times \( t_1, t_2, \ldots, t_i \) and a second series of readings \( S'_1, S'_2, \ldots, S'_j \) is made at the corresponding times \( t_1 + \Delta t, t_2 + \Delta t, \ldots, t_i + \Delta t \) (where \( \Delta t \) is a constant of magnitude of the order of one half-life) then Equation (9) follows

\[
(S_\infty - S'_i) = (S_\infty - S_0)e^{-kt_i}
\]

and Equation (10)

\[
(S_\infty - S'_j) = (S_\infty - S_0)e^{-k(t_i + \Delta t)}
\]

After subtracting Equation (10) from Equation (9), obtaining the logarithms and assuming that \( S_\infty, S_0, \) and \( \Delta t \) are constants, we have Equation (11)

\[
\ln|P'_i - P'_j| = constant - kt_i
\]
from which by plotting the left-hand function versus \( t_i \) a straight line is obtained with a slope equal to \(-k\) (or \(-k_{obs}\)). For the application of the Guggenheim method the reaction should obey first-order kinetics over at least two half-life periods.

The partial order in a given reactant will be unity if a plot of initial rate versus reactant concentration is a straight line; in fact, at \( n = 1 \), Equation (3) is representative of a straight line of zero intercept.

2 DETERMINATION OF A SINGLE COMPONENT – PRINCIPLES OF METHODS AND TECHNIQUES(1–8)

The determination of the analyte A based on the second-order reaction described by the rate Equation (1) can be performed under two limiting conditions: (1) in the case of R being in large excess (over a 50-fold) relative to the analyte (A), then the reaction will proceed under pseudo-first-order in respect to A or (2) in the case of R being in large excess (over a 50-fold) relative to the analyte (A), the reaction will proceed under second-order conditions.

The various approaches used in the determination of a single noncatalytic species are shown in Table 1 and discussed in detail below.

2.1 Pseudo-first-order Conditions

The general differential rate expression of a reaction under pseudo-first-order conditions in respect to the analyte, A, is Equation (12):

\[
\text{rate} = -\frac{d[A]}{dt} = \frac{d[P]}{dt} = k[A][R]_0 = k_A[A] \tag{12}
\]

where \( k_A = k[R]_0 \). Equation (12) is normally the basis for the kinetic determination of A under pseudo-first-order conditions.

Table 1 Analytical approaches used in kinetic determinations of single noncatalytic species

In the case of initial-rate approach, the rate expression (Equation 12) can be written in incremental form as Equation (13):

\[
\text{rate} = -\frac{\Delta[A]}{\Delta t} = k_A[A]_0 \tag{13}
\]

from which the concentration of the analyte A can readily be calculated. In this approach, the rate of signal change is measured (or computed) and related to the analyte concentration. Assuming that the analyte is the rate determining reactant (R is in excess), the relationship can be represented as Equation (14)

\[
\text{rate} = \frac{\Delta S}{\Delta t} = bk[A]_0 \tag{14}
\]

where \( b \) is the sensitivity factor. Calibration standards are usually used to obtain a calibration constant representing the proportionality factor, \( bk \). In such procedures, changes in any variable (e.g. temperature, pH) that would affect the rate constant would produce an error in the determined concentration.

The principles of fixed-time and variable-time approaches are based on Equation (15) which is the exponential expression of Equation (12):

\[
\text{rate} = -\frac{d[A]}{dt} = k_A[A]_0 \exp(-kt) \tag{15}
\]

Assuming that \( t_2 = t_1 + \Delta t \), the integration of Equation (15) over an interval \( t_2 - t_1 \) results in Equation (16)

\[
[A]_0 = \frac{-\Delta[A]}{\exp(-k_A t_1)[1 - \exp(-k_A \Delta t)]} \tag{16}
\]

In the fixed-time approach \( t_1 \) and \( \Delta t \) are kept constant, thus, as stated from Equation (16) a linear relationship exists between \( \Delta[A] \) and \( [A]_0 \). In a one-point/fixed-time approach, the detector signal, \( S_t \), is measured at some fixed point in time after the reaction (process) is initiated. In such procedures applied to first-order reactions, the background signal, \( S_0 \), is assumed to be zero and analyte concentration is determined from a single proportionality of the form (Equation 17)

\[
[A]_0 = \frac{S_t}{b[1 - \exp(-k_A t_1)]} \tag{17}
\]

where \( b \) is the sensitivity factor. The calibration constant, \( [1/b[1 - \exp(-k_A t_1)] \) is evaluated by calibration standards or calibration plots. The one-point option cannot compensate for background (blank) signals and it cannot detect unexpected changes in kinetic behavior. Any change in variables that would affect the rate constant would also affect the calibration constant and computed concentration. The one-point/fixed-time approach
is seldom used now because it does not compensate for changing backgrounds.

The two-point/fixed time option is perhaps the most widely used approach for kinetic determinations. In this approach, two signal values, \( S_1 \) and \( S_2 \), are measured at two points in time, \( t_1 \) and \( t_2 \), and the difference, \( \Delta S = S_1 - S_2 \), is used to compute the concentration. The mathematical description for a first-order process is easily shown to be Equation (18)

\[
[A]_0 = \frac{\Delta S_{\infty}}{b} = \frac{\Delta S_t}{b[\exp(-kA_{t1}) - \exp(-kA_{t2})]} \quad (18)
\]

In the most common applications of this approach, the calibration factor in the denominator of the term at the far right-hand side of the expression is determined by using calibration standards. This option compensates for background signals but, like the one-point option, cannot detect unexpected changes in kinetic behavior.

In the variable-time approach the quantity \( \Delta [A] \) is kept constant. According to Equation (16) \( \Delta t \) and \( t_1 \) depend on \( [A]_0 \), therefore the analyte concentration \( [A]_0 \) under determination will never be linearly related to \( 1/\Delta t \). In this situation the error will be minimized if \( [A]_1 \) is almost equal to \( [A]_0 \) and therefore \( \exp(-kA_{t1}) \rightarrow 1 \) and at short reaction times (small \( \Delta[A] \) and \( \Delta t \to 0 \)) Equation (16) can be linearized since \( [1 - \exp(-kA\Delta t)] \) can be simplified to \( k\Delta t \) by expanding the exponential function as a Maclaurin series. In this option, the measurement objective is the time interval, \( \Delta t \), required for the reaction (process) to proceed to a predetermined extent.

In the one-point/variable-time approach the quantity measured is the time interval between the start of a reaction and some predetermined point in the reaction, usually completion. An early example of this option is the so-called “stop-watch method”.

In the two-point/variable-time approach, the measurement objective is the time interval between two predetermined signal values. The time interval is used to compute concentration. This option has some interesting features and has been used in automated kinetic potentiometric methods using a double switch system. A physicochemical analog involves a flow-injection (FI) approach in which the measured quantity is the time required for the detector signal to change between two predetermined points on a response profile (FI pseudo titrations). A plot of \( \Delta t \) versus log \( [A]_0 \) is linear.

In the above approaches, knowledge of the relationship between concentration and the detector signal is not required and the dynamic range can be extended by control of reagent concentration.

In the signal-stat approach, the detector signal is used to indicate when a property (e.g., pH) has changed outside some predetermined narrow limits and a reagent (e.g., acid or base) is added to return the property to within the desired limits. The quantity of reagent needed to maintain the measured property within the desired limits is measured and used to compute the analyte concentration. Therefore, the time-dependent addition of reagent reflects the time course of the reaction. Usually multiple additions of reagent are required so that a multiple response curve is available. The most common version of this approach is the pH-stat option but the concept should be applicable to the control of any reactant.

In conclusion, the fixed-time approach ensures wider dynamic concentration ranges than does the variable-time approach for first- or pseudo-first-order conditions.

### 2.2 Second-order Conditions

The rate of a reaction under second-order conditions is dependent on the concentrations of two reactants. The expression for the reaction rate is Equation (19)

\[
\text{rate} = -\frac{d[A]}{dr} = -\frac{d[R]}{dr} = \frac{d[P]}{dr} = k[A][R] \quad (19)
\]

In the case of equal concentrations of the two reactants, \( ([A]_0 = [B]_0) \), Equation (19) becomes Equation (20):

\[
\text{rate} = -\frac{d[A]}{dr} = k[A]^2 \quad (20)
\]

Integration of Equation (20) in the time interval zero and \( t \) results in the linear expression Equation (21):

\[
\frac{1}{[A]} = \frac{1}{[A]_0} + kt \quad (21)
\]

from which the analyte concentration \( [A]_0 \) can be estimated directly.

In the case of an analytical reaction under second-order conditions in which the concentrations of the two reactants are different, integration of Equation (19) between \( t_1 = 0 \) and \( t_2 = t \) results in the general second-order integrated rate expression (Equation 22):

\[
\ln \frac{[R]}{[A]} = \ln \frac{[R]_0}{[A]_0} + ([R]_0 - [A]_0)kt \quad (22)
\]

A plot of the left-hand term \( \ln([R]/[A]) \) versus time will be linear and the analyte concentration \( [A]_0 \) can be readily calculated from the intercept and the known value of \( [R]_0 \).

### 2.3 Multipoint Approaches

The wide availability of computers with high processing power which usually are used on-line with the analytical instruments of kinetic analysis has promoted the development of various powerful approaches based
on the efficient use of the full analytical information from the reaction curve. These include a curve-fitting approach, a predictive approach and an error-compensated approach.

A curve-fitting approach computes modified signals in order to obtain the best fit for a mathematical model describing the transient process. The least-square procedure is widely used for this purpose.

A predictive approach takes advantage of a large number of experimental data to calculate the best estimate for the signal change to be expected if the reaction system were allowed to reach equilibrium \( S_\infty \), using linear or nonlinear least-squares or the Kalman filter. The object of the curve-fitting process would be to obtain best-fit values of \( S_0 \), \( \Delta S_\infty \), and the rate constant, \( k \). Thus, in a single data-processing step, it is possible to compensate intrinsically for variables that affect rate constants.

An error-compensated approach minimizes the marked dependence of the transient signal of the reaction system from experimental variables. Various mathematical algorithms or simultaneous measurements of analytical signals and the variable(s) affecting the system are used in order to establish pertinent corrections.

### 2.4 Techniques of Mixing and Monitoring

Kinetic methods are performed using instruments of various complexity, from conventional simple systems such as photometers, fluorimeters or potentiometers to highly sophisticated fully automated systems, capable of sample aliquoting, transferring to the detector, signal collecting and manipulating, and processing the results obtained.

Depending on the type of system concerned, several techniques are used for mixing of the reactants to start the analytical reaction.

#### 2.4.1 Conventional Simple Techniques

Slow chemical reactions can be followed using simple spectrophotometric, fluorimetric or potentiometric systems, usually equipped with thermostatted observation cells, and manual mixing and/or magnetic or mechanical stirring.

#### 2.4.2 Stopped-flow Technique

In the stopped-flow (SF) technique a prepared sample solution is mixed rapidly and efficiently with a prepared reagent solution by means of two driving syringes that are actuated manually or by a pneumatic device, through a mixing-chamber into a flow-cell which can also serve as the observation cell. The flow is stopped abruptly by using a third stopped syringe and the analytical signal (usually absorbance or fluorescence) is then recorded as a function of time. This technique is ideal for performing fast reactions with half-lives of a few milliseconds to several seconds. Its performance depends mainly on the dead time (mixing time).

#### 2.4.3 Flow-injection technique

Flow-injection analysis (FIA) has been defined as “information gathering from a concentration gradient formed from the injected, well-defined zone of a fluid, dispersed into a continuous unsegmented stream of a carrier”. Therefore, all chemical assays performed by FIA can be said inherently and necessarily to entail the utilization of chemical kinetics. Under FIA conditions it is possible to utilize masks which operate on a time-based mode, taking advantages of the differences in kinetic rates between the mask and the interferent or analyte. FIA can operate in a continuous-flow, SF, recycle flow or reversal flow mode. Reactions producing unstable intermediates can be easily adapted in the FIA technique.

In the continuous-flow mode a signal peak is obtained after a preselected time interval (fixed-time approach). If an external mixer is used a wide signal peak is obtained capable of being used in the two-point/variable-time approach. In the SF mode (FI/SF) the reacting mixture is stopped in the detector cell at time \( t_1 \) and the signal is monitored during a \( \Delta t \) time interval (reaction rate or slope approach). In the recycle flow mode, as denoted by its name, the reacting plug is passed several times through the flow detector in the same direction providing a multipeak response whose envelope represents the profile of the kinetic curve. In the reversal flow mode, the reacting plug is also passed several times through the flow detector but alternately in opposite directions, which provides a response similar to that of the recycle flow mode.

#### 2.4.4 Continuous Addition of Reagents Technique

The continuous addition of reagents (CAR) technique is based on the continuous addition at a constant rate of one of the reaction components (usually the reagent) in the reaction cell equipped with a stirring device. The reaction curve (absorbance or fluorescence as function of time) is recorded simultaneously with the aid of an automated computer-controlled system.

#### 2.4.5 Stat Technique

This technique, which is suitable for slow reactions, is based on the addition of microamounts of a reactant to the reaction cell at a known rate such that an analytical
parameter of the monitored reaction (pH, absorbance, luminescence, etc.) is maintained constant. Any deviation from this state because of the reaction processing is immediately compensated for by automatically adding an extra amount of the reactant. The rate of addition is used to estimate the reaction rate.

2.4.6 Centrifugal Mixing

This technique is used in parallel fast analyzers. Microvolumes of samples and reagent(s) are added in microwells on a removable rotating disk. The disk is placed in a centrifuge rotor. When the rotor spins, mixing is induced by the action of the centrifugal force, which finally displaces the mixed solution into the observation cell. The technique provides a great number of data during the observation time.

2.5 Detection Systems

The course of a reaction can be monitored by chemical or visual means, but mainly by instruments (photometric, fluorimetric, chemiluminometric, electroanalytical devices). A large number of reactions involve substances that absorb in the near-ultraviolet or visible region. Rapid scanning spectrometry (vidicon image detector, photodiode array) offers an attractive potential for kinetic methods of analysis. Ion selective electrodes (ISEs) are of special use in potentiometric techniques as applied to kinetic analysis on account of their usually high sensitivity to concentration changes and the freedom from optical interferences.

3 REACTION TYPES

The various reactions used in kinetic-based noncatalytic determinations of single species can be categorized into several groups, which are described in detail below.

3.1 Complexation Reactions

This group includes both formation and substitution reactions, mainly applied to inorganic analytes.

3.1.1 Substitution Reactions

Kinetic methods based on substitution reactions involve either a ligand or a metal displacement from a starting complex:

- **Ligand substitution reaction** $ML_1 + L_2 \rightarrow ML_2 + L_1$
- **Metal substitution reaction** $M_1L + M_2 \rightarrow M_2L + M_1$

The ligand exchange between Cu(II) complex with 2-(2-thiazolyazo)-5-dimethylaminophenol and ethylene-diaminetetraacetic acid (EDTA) is the basis of a spectrophotometric kinetic method for copper. The substitution of Cu(II) by Ga(III) in the copper–EDTA complex is the basis for a spectrophotometric kinetic method for Ga(III). The exchange between Th–DCTA (diaminohexanetetraacetic acid) complex and the attacking ligand arsenazo(III) can be used for the kinetic spectrophotometric determination of thorium.

The kinetic spectrophotometric determination of chloride using FI mixing and fixed-time approach is based on the following scheme of reactions, Equation (23) and (24):

$$2Cl^- + Hg(SCN)_2 \rightleftharpoons HgCl_2 + 2SCN^- \quad (23)$$
$$SCN^- + Fe^{3+} \rightleftharpoons Fe(SCN)^{2+} \quad (24)$$

The displacement of fluoride from its aluminum complexes by EDTA, citrate and $\alpha$-hydroxyacids is the basis for their potentiometric kinetic determination using fluoride ISE.

3.1.2 Complex formation Reactions

This type of reaction is mainly used for the determination of a single metal ion or an organic substance acting as a ligand. The complexation of iron(III) with thiocyanate is the basis of a spectrophotometric kinetic method for Fe(III). Aluminum can be determined by an initial rate fluorimetric method based on its chelation with 2-hydroxy-1-naphthaldehyde $p$-methoxybenzoylhydrazone. $O$-Cresolphthalein complex-one is used as the complexing agent for the spectrophotometric determination of calcium using the SF technique. The complexation of magnesium by calmagite in alkaline medium and in the presence of bis(aminooethyl)glycethere-$N,N',N''$-tetraacetic acid (EGTA) to mask calcium is the basis of a spectrophotometric kinetic method for magnesium.

A selective kinetic spectrophotometric method for zinc is based on its complexation with zinc which follows the differential demasking of the cyanide complexes with cyclohexanone, Equation (25) and (26):

$$[Zn(CN)_4]^{2-} + 4C_6H_{10}O + 4H_2O \rightarrow Zn^{2+} + 4C_6H_{10}(OH)CN + 4OH^- \quad (25)$$
$$Zn^{2+} + \text{zinc} \leftrightarrow \text{blue complex} \quad (26)$$

The formation of molecular complexes has been used in organic kinetic analysis. The reaction of albumin with picrates monitored with a picrate ISE has been
proposed for the determination of albumin in serum. The formation of the characteristic yellow–orange complex of creatinine with alkaline picrate has been the basis of its spectrophotometric or potentiometric (using a picrate ISE) kinetic determinations.

Of special interest are the immunochromosomal reactions of antigen and hapten with their antibodies. Several drugs of abuse are determined using the fluorescence polarization technique. The specific precipitation of lipoprotein by heparin, calcium ions, EDTA and lipase is the basis of a turbidimetric kinetic method.

3.2 Redox Reactions

Redox reactions have been mainly used for the determination of anionic rather than cationic species in inorganic analysis.

The reduction of iodate to iodine by arsenite in strongly acidic medium is used in an initial-rate spectrophotometric SF method for arsenite. Iodide can be oxidized by perbromate to triiodide complex, I$_3^-$, the spectrophotometric (353 nm) monitoring of which is the basis for the kinetic determination of perbromate (0.3–3 μg). The competitive equilibria of oxidation and complexation between the benzyl 2-pyridyl ketone 2-pyridylhydrazone, bromate and copper(II), nickel(II) and palladium(II) cations is the basis for the spectrophotometric kinetic method (initial rate approach) for these cations. The reduction of Mo(VI) by hydrazine in acidic medium can be used for the kinetic spectrophotometric determination of hydrazine.

The kinetic determination of iodide (0.6–7 ng mL$^{-1}$) is based on its reaction with acetone in alkaline medium to form iodoform and iodide which is monitored with an iodide ISE (initial rate approach) Equation (27):

$$\text{(CH}_3\text{)}_2\text{CO} + 3\text{I}^- + 4\text{OH}^- \rightarrow \text{CH}_3\text{I} + \text{CH}_3\text{COO}^- + 3\text{I}^- + 3\text{H}_2\text{O} \quad (27)$$

The oxidation of 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulphonate in alkaline medium by manganese in the form of hydrated MnO$_2$ is the basis for a fluorimetric kinetic method for Mn.

The well-known Karl Fischer reaction for water is the basis for its kinetic SF spectrophotometric determination (1–10 mg mL$^{-1}$) using an acetate pyridine-free reagent, Equation (28):

$$\text{CH}_3\text{SO}_3\text{I}_2^- + \text{H}_2\text{O} \rightarrow \text{CH}_3\text{SO}_4^- + 2\text{I}^- + 2\text{H}^+ \quad (28)$$

Redox reactions are of special interest in organic analysis and rely on the oxidation of organic compounds by a strong oxidant such as permanganate, cerium(IV), iron(III), periodate, dichromate, hexacyanoferrate(III), peroxydisulfate, or hydrogen peroxide.

Periodate is a common oxidant for organic hydroxy compounds including phenols, chlorophenols, hydroxyacids (e.g. tartaric acid) and vicinal glycols (e.g. glycerol) (Malaprade reaction), Equation (29):

$$\text{A} + \text{IO}_4^- \rightleftharpoons \text{A} \cdot \text{IO}_4^- \rightarrow \text{products} \quad (29)$$

where A \cdot \text{IO}_4^- is an intermediate (periodate ester). Fixed-time (absorbance measurements) and variable-time (perchlorate or home-made periodate-selective electrode) methods can be used for the determination of these species and related substances such as carbohydrates (e.g. glucose).

Peroxydisulfate oxidation of organic carbon is the basis for an automated determination of organic carbon in water samples.

One interesting redox reaction is the reversible interconversion of ferrin/ferroin complexes. The 1,10-phenanthroline/iron(III) complex (ferriin) has been used to oxidize species of clinical (uric acid) and pharmaceutical interest such as anagelseics (acetaminophen) and catecholamines, the reaction being monitored by measuring the initial rate change of the absorbance of the ferroin at 510 nm. The ligand 2,4,6-tris-(2-pyridyl)-s-triazine (TPTZ) has also been used.

The oxidation of various organic substances (carbamazepine, choline, acetylcysteoline) with Ce(IV) in acidic medium yields fluorescent Ce(III) species used for their kinetic fluorimetric determination. Carbimazole is oxidized to a colored product using dichromate or molybdate at 90°C.

The oxidation of various organic analytes (alcohols and carbohydrates) with dichromate in acidic medium can be monitored with a home-made dichromate ISE and used for their kinetic determination.

The formation of colored unstable free radicals yielded during the oxidation of phenothiazines (chlorpromazine, methotrimiprazine, thiourazide, etc.) with Fe(III) in acidic medium has been used for their spectrophotometric kinetic determination.

The Mn(II)-catalyzed oxidation of oxalate with permanganate has been used for a fast kinetic spectrophotometric determination of oxalate.

Bromosuccinimide oxidizes several organic compounds such as vitamins (pyridoxine, thiamine, ascorbic acid), being reduced to succinimide with the liberation of bromide which can be monitored with a bromide ISE.

3.3 Coupled Reactions

The most typical example of this type of reaction is the so-called Griess reaction, originally developed for the kinetic determination of nitrite. Nitrite in a weakly acidic solution reacts with an amine (usually
sulfanilic acid) to form the corresponding diazonium salt, which then couples with a naphthylamine derivative or naphthol. This reaction can be used for the kinetic determination of nitrate after reduction in a column (copperized cadmium), as well as for measuring other species such as sulfonamides (the Bratton–Marshall reaction), bromhexine, benzodiazepines (e.g. nitrazepam) and N-methylcarbamate pesticides, hydrolysis of which yields the corresponding benzophenones (which can be diazotized) and naphthols (useful for the coupling reaction), respectively. Nitroprusside liberates nitrite in alkaline medium and can be determined kinetically using the Griess reaction.

The well-known Berthelot reaction of ammonia is the basis for various kinetic methods for ammonia–nitrogen. Ammonia reacts with hypochlorite to form chloramine which then is coupled with phenol in two steps to form indophenol blue, Equations (30–32):

\[
\begin{align*}
\text{NH}_3 + \text{OCl}^- & \rightarrow \text{NH}_2\text{Cl} + \text{OH}^- \\
2\text{OCl}^- + \text{NH}_2\text{Cl} + \text{C}_6\text{H}_5\text{O}^- & \rightarrow \text{OC}_6\text{H}_4\text{NCl} \\
& \quad + 2\text{Cl}^- + \text{OH}^- + \text{H}_2\text{O} \\
\text{OH}^- + \text{OC}_6\text{H}_4\text{NCl} + \text{C}_6\text{H}_5\text{O}^- & \rightarrow \text{OC}_6\text{H}_4\text{NC}_6\text{H}_5\text{O}^- \\
& \quad + \text{H}_2\text{O} + \text{Cl}^- 
\end{align*}
\]

Aminoglycoside antibiotics (amicacin, kanamycin, tobramycin), through their primary amine group, participate in a cyclization reaction with o-phthalaldehyde and a thiol to form a 1-alkylthio-2-alkylisoindole fluorescent derivative which can be used for their kinetic determination.

Oxidative coupling reactions of p-phenylenediamines (PPD) with amines and phenols are widely used. PPD is oxidized to its quinone diimine (QDI) by hexacyanoferrates(III) or a similar oxidant in a weakly basic medium. QDI reacts with the amine or phenol compound to give leucoindamines (leucoindophenols), which are rapidly oxidized to colored indamines (indophenols) with the aid of a QDI molecule.

The reduced form of ascorbic acid (dehydroascorbic acid) obtained using Hg(II) reacts with o-phenylenediamine to form fluorescent quinoxaline. The oxidative condensation of para- and meta-substituted phenols with 1-nitroso-2-naphthol using Ce(IV) or Pb(IV) can be used for the kinetic spectrophotometric determination of phenols.

The so-called bromination reactions use bromine generated in situ from BrO⁻⁻/Br⁻ couple in an acidic medium. At low analyte concentrations, the rate of bromination and bromine generation are virtually the same, so methyl orange in the reaction medium will only be decolorized after the bromination process has been completed. The decolorization time will be proportional to the analyte (e.g. acetaminophen) concentration. Bromide can be determined in addition to phenol compounds, which are the typical substrates.

The bromination of the yellow indicator phenol red (PR) to bromothymol blue (BTB) at pH 4.6 using bromine produced by the oxidation of bromide with chloramine-T is the basis for a kinetic determination of bromide using FI mixing and the fixed-time approach, Equations (33) and (34):

\[
\begin{align*}
2\text{Br}^- + \text{H}_3\text{C} - \text{C}_6\text{H}_5\text{SO}_2\text{NCl}^- + 2\text{H}^+ & \rightarrow \text{Br}_2 + \text{H}_3\text{C} - \text{C}_6\text{H}_5\text{SO}_2\text{NH}_2 + \text{Cl}^- \\
4\text{Br}_2 + \text{PR} & \leftrightarrow \text{BTB} + 4\text{H}^+ + 4\text{Br}^- 
\end{align*}
\]

### 3.4 Addition Reactions

Formation of addition compounds from species containing carbonyl groups has been exploited for the determination of organic compounds reacting with hydrogen sulfitre ion in the presence of acetone, methanol or acetic acid. The addition reaction of sulfitre with rosaniline at pH 11.8 has also been used for the kinetic spectrophotometric determination of sulfitre. The addition reaction of hydrogen cyanide to carbonyl group (e.g. formaldehyde) monitored with a cyanide ISE has been used for its kinetic determination. Aromatic aldehydes have been determined spectrophotometrically using their condensation reaction with barbituric acid. Primary and secondary amines (e.g. amphetamine, ephedrine) react with 1,2-naphthoquinone-4-sulfonate to form a colored product which is the basis for their kinetic determination. The reaction of amino acids with ninhydrin (a dihydroxynindanedione) at 80°C is the basis for their kinetic photometric method. Tryptophan reacts with formaldehyde in alkaline solution to form a highly fluorescent product.

Urea reacts with the unstable diacetyl (produced in situ by the acidic hydrolysis of diacetyl monoxime) to form a yellow diazine derivative.

### 3.5 Aromatic Substitution Reactions

Several reagents capable to undergo aromatic substitution reactions with various substances owing reactive functional groups have been proposed for the kinetic determination of these substances. A characteristic example is the reaction of 1-fluoro-2,4-dinitrobenzene (FDBN) with amines, amino acids, phenols, thiols, hydrazines, and hydrazides. The reaction, through the formation of an intermediate complex (Meisenheimer complex)

LOD, limit of detection; CF/SF, continuous flow/stopped flow; NEDD, N-(1-naphthyl)ethylenediamine dihydrochloride.

leads to the formation of a dinitrobenzene (DNB)-derivative (capable of spectrophotometric monitoring) and the release of fluoride ion (capable of potentiometric monitoring with a fluoride ISE) Equation (35):

\[
\text{RNH}_2 + (\text{NO}_2)_2\text{C}_6\text{H}_3\text{F} \iff (\text{NO}_2)_2\text{C}_6\text{H}_3(\text{F})\text{NH}_2\text{R} \\
\rightarrow (\text{NO}_2)_2\text{C}_6\text{H}_3\text{H}_2\text{NHR} + \text{H}^+ + \text{F}^- \quad (35)
\]

These rather slow reactions can be accelerated by cationic surfactants using micellar catalysis. Several spectrophotometric and potentiometric methods using manual or FI mixing have been proposed for a great number of substances of pharmaceutical interest.

The nucleophilic substitution reaction of trinitrobenzenesulfonate (TNBS) with amino acids and carbohydrates in an alkaline medium monitored with a TNBS home-made ISE has been used for the kinetic determination of the analytes, Equation (36):

\[
\text{RNH}_2 + (\text{NO}_2)_3\text{C}_6\text{H}_2\text{O}^- \iff (\text{NO}_2)_3\text{C}_6\text{H}_2^-\text{NHR} \\
\rightarrow (\text{NO}_2)_3\text{C}_6\text{H}_2\text{H}_2^-\text{NHR} + \text{SO}_4^{2-} + \text{H}^+ \quad (36)
\]
3.6 Hydrolysis Reactions

Several hydrolysis reactions have been used for kinetic-based determinations. The alkaline hydrolysis of furazolidone, furaltadone, and methyl parathion can be used for their spectrophotometric kinetic determination. The oxidative (H₂O₂) alkaline hydrolysis of chlopyrifos is the basis for its kinetic determination. The alkaline hydrolysis of p-chloranil yields chloranilate which can be monitored with a chloranilate home-made ISE.

The acid degradation with heating of tetracycline and oxytetracycline to the anhydro derivatives is the basis of their spectrophotometric determination.

3.7 Chemiluminescence Reactions

While the main field of application of chemiluminescence (CL) reactions is catalytic processes (determination of inorganic catalysts and various inhibitors) and sensitization processes (by energy transfer and stabilization), some noncatalytic reactions are also of great interest on account of the high sensitivity they provide. Some characteristic examples of such reactions are that of hypochlorite with luminol for the determination of hypochlorite, the reaction of acetaminophen with Ce(IV) in acidic medium, and the reaction of ethanol with MnO₄⁻ in very acidic solutions.

4 ANALYTES DETERMINED(5,9–11)

4.1 Determination of Inorganic Species

Complex formation and redox reactions are mainly used for the determination of metals and nonmetals. Table 2 presents selected kinetic methods for inorganic species. The majority of these methods are based on photometric detection and the concentration ranges typically are in the micrograms per milliliter region.

4.2 Determination of Organic Species

Kinetic methods of analysis based on noncatalyzed reactions are very attractive in organic analysis, since they generally lack a catalytic activity. All types of reactions have been used in kinetic organic analysis and the majority of the reactions are monitored spectrophotometrically and fluorimetrically. Table 3 shows selected examples of kinetic methods employed in organic analysis.

5 APPLICATION AREAS

The increased automation of kinetic methods, especially in organic analysis, using a variety of commercial or home-made analyzers of various types (FI, SF, etc.) has resulted in a tremendous increase in the use of noncatalytic kinetic methods. The advantages of short analysis time, high precision and the absence of serious interferences make the application of uncatalyzed kinetic methods very attractive for routine analysis of real samples in a variety of areas. Clinical, environmental, food and pharmaceutical analysis are the areas where kinetic methods are applied with success and are discussed below.

5.1 Clinical Analysis

The following inorganic and organic species can be determined in serum and/or urine using kinetic methods based on noncatalytic reactions:

- **Serum:** Aluminum, bromide, calcium, magnesium, nitrate, phosphate, thiocyanate, acetaminophen, ascorbic acid, carbamazepine, malonaldehyde. Albumin, creatinine, lipoprotein, total serum protein, urea, uric acid, hemoglobin, methemoglobin, reduced glutathione.

- **Urine:** Nitrate, phosphate. Amphetamines, ascorbic acid, morphine, sulfonamides. Catecholamines, creatinine, uric acid.

Some of the methods can be applied directly on the biological sample (urea, uric acid and phosphate) but others required treatment (protein precipitation, liquid–liquid extraction, solid-phase extraction (Sep-Pack cartridges) etc.). The detectability and sensitivity of the kinetic methods are suitable so that a rather low volume of sample is required (20–500 µL of serum). Most kinetic methods can be performed using automated clinical analyzers (centrifugal, batch, and flow analyzers).

5.2 Environmental Analysis

The application of kinetic methods in this area is extensive. The sample matrix (natural-, waste- and seawaters) is simple allowing direct determinations without any treatment. Water and air samples can very easily be analyzed using automated apparatus.

The following species, most of them being inorganic, can be determined in various environmental samples using noncatalytic kinetic methods:

- **Air:** carbon dioxide, manganese, nitrogen oxides.

- **Natural waters:** arsenite, hydrazine, hypochlorite, iodine, magnesium, manganese, nitrates, nitrite,

### 5.3 Food Analysis

Several inorganic and organic species can be determined in a variety of food samples. Special treatment of the sample is required before the application of the kinetic method. The most frequently determined species are ascorbic acid, iron and phosphate. The following species can be determined using uncatalyzed kinetic methods in food sample: calcium, iron, magnesium, crude protein, phosphorus, tryptophan, sulfonylamides (animal feed), ascorbic acid (juices, green tea, potatoes, red pepper, spinach and strawberry), aluminum (spinach and tea leaves), aspartame (beverages), bromate (bread), butylated hydroxyanisole (vegetable oils), ethanol (gin and beverages), iron (wines), malonaldehyde (olive oil), nitrite (liver oil, cured meat), organic peroxides (oils), sucrose (milk and soft drinks), sulfite (beverages, biscuits, steamed buns), tryptophan (vegetables and fish).

### 5.4 Pharmaceutical Analysis

The quality control of drugs (assay of content, content uniformity, dissolution studies) requires a great number of determinations and automated kinetic methods are...
attractive for this purpose. All kind of pharmaceutical formulations (capsules, injections, ointments, tablets, syrups) have been analyzed for several drugs using kinetic methods without serious interference from the excipients. Potentiometric kinetic methods using ISEs can be successfully applied in colored and cloudy sample solutions. The FIA has found tremendous use in routine pharmaceutical analysis using kinetic methods and has been successfully employed in dissolution studies of solid formulations (tablets and capsules), providing complete dissolution profiles.

The following drugs have been determined in pharmaceutical formulations: acetaminophen, aminoglycoside antibiotics, amoxicilline, amphetamine, ascorbic acid, benzocaine, bismuth, boric acid, bromazepam, bromhexine, bromide salts of drugs, carbinazole, catecholamines, chloride salts of drugs, chlorpromazine, corticosteroids, cyanocobalamin, ephedrine, furazolidone, furalatadone, hexamethylenetetramine, isoniazid, isosuprine, methotrimeprazine, morphine, nitrazepam, nitroglycerine, nitroprusside, nortriptylin, oxazepam, phenazine, phenothiazines, procaine, salicylamide, sulfonamides, tartaric acid, tetracyclines, thiamine, thioridazine, theophylline, zinc.

Liquid Chromatography: Introduction

John G. Dorsey
Florida State University, Tallahassee, USA

Liquid chromatography is more than likely the most used method of analysis for compounds in solution. Entire industries depend on the separation power of this modern analytical technique: walking through any pharmaceutical company in the world will show a liquid chromatograph on almost every bench! Yet chromatography by its nature can be thought of as a necessary evil. That is, it is a dilution technique which takes some length of time to occur. In other words, we apply a certain concentration of a sample to the top of a column, wait for seconds or minutes, and then try to detect a lower concentration of the components in the mixture! The rationale for this process is the elegant separations possible. If the other analytical techniques were selective enough, there would be no need for chromatographic separations. This is not likely to occur anytime soon, except for the simplest mixtures. It is still easier to detect a lower concentration of a pure component in a solvent stream than to measure it selectively in a complex mixture. Chromatography can also be thought of as a violation of the second law of thermodynamics. Mother Nature favors mixtures and we are asking her to let us perform a separation. The price she extracts is in either concentration or recovery, and we must pay in one currency or the other.

Since its invention in 1906 by Tswett, liquid chromatography has changed dramatically in terms of understanding and controlling the chemistry of the separation process, yet it has also remained virtually unchanged in its form. A translated paragraph from Tswett’s first publication in a Russian botany journal is fascinating:

“If a petroleum ether solution of chlorophyll is filtered through a column of an adsorbent (I use mainly calcium carbonate which is stamped firmly into a narrow glass tube), then the pigments according to the elution sequence are resolved from top to bottom into various colored zones, since the stronger adsorbed pigments displace the weaker adsorbed ones and force them farther downwards. This separation becomes practically complete if, after the pigment solution has flowed through, one passes a stream of pure solvent through the adsorbent column. Like light rays in the spectrum, so the different components of a pigment mixture are resolved on the calcium carbonate column according to a law and can be estimated on it qualitatively and also quantitatively. Such a preparation I term a chromatogram and the corresponding method, the chromatographic method.”

We have instrumentalized the technique, miniaturized the technique, and have learned to control the chemistry of the mobile and stationary phases, yet in the simplest terms the technique as practiced today has changed very little from that earliest description.

The articles that follow encompass all of the important methods and concepts of this separation technique, and are authored by some of the world’s leaders. From stationary phase chemistry to separation mechanisms to electrophoresis, thin-layer chromatography and supercritical fluid chromatography, we have attempted to cover all of the important areas. Entire volumes could be (and have been!) written on each of these subjects. By necessity we have limited the coverage to the basics while maintaining breadth.

Affinity Chromatography is one of the most selective of the separation methods, and can be thought of as “digital” chromatography. That is, a column is designed to retain a specific analyte, or very closely related analytes, while everything else in the sample is unretained. The analyte of interest is then “released” from the column and quantitated. While simple in description, the design of highly selective columns is very challenging!

The article Biopolymer Chromatography shows the power of the technique for the analysis of biological compounds. Biology and chemistry are merging, and the chemical analysis of complex biological systems has opened entire new frontiers to analytical chemists. Separations of polypeptides, proteins, and even cells are possible, but challenging. A protein will interact differently with a stationary phase in its native and denatured form, may denature upon contact with some stationary phases, and gives different retention times and peak shapes depending upon its conformation. In fact, column chromatography has been used to measure denaturation rate constants!

Capillary Electrophoresis is the newest high-resolution separation method, and grew very rapidly through the 1980s and 1990s. However, the sale of instruments has remained virtually flat since the introduction of commercial instrumentation in 1989, while the growth of publications has been almost exponential. Is this just a toy for academicians? It is a very important tool for the bio-tech industry, for DNA sequencing, and other specialized separations, but will likely never be the replacement for liquid chromatography that some originally thought.

The human body is chiral, and because of this both the study of life processes and the design of efficacious pharmaceutical compounds require efficient separations of racemic mixtures. The separation of optical isomers has been a great challenge for separation chemists. Yet that most sensitive of “analytical methods”, the human body, can tell immense differences between the
two forms. The thalidomide tragedy in Europe in the 1960s is but one example. While one enantiomer of this compound was efficacious against morning sickness, the other was a teratogen, and since the compound was made as a racemic mixture, hundreds of children were born seriously deformed. The article Chiral Separations by High-performance Liquid Chromatography describes what we have learned, and what is left to accomplish.

A fundamental article, Column Theory and Resolution in Liquid Chromatography, describes the fundamental processes that occur inside the column, and the terminology that is used to describe the quality of separations.

Most real separations cannot be performed with a single composition mobile phase. That is, the range of solutes is so broad that any given mobile phase will be too "strong" for some solutes, providing little or no resolution, and will be too "weak" for others, letting them move through the column too slowly, if at all. The article Gradient Elution Chromatography describes this most used solution to the "General Elution Problem", and shows both theory and methodology for speeding separations.

While most people think of chromatography for the separation of neutral organic molecules, there is also much need for the analysis of charged species; from simple inorganic ions in plating plants and waste-treatment processes, to charged biopolymers. The article Ion Chromatography discusses the development of this very important chromatographic method, both in terms of separations but also in terms of detection of compounds that may have no chromophore.

Capillary electrophoresis is an efficient method for the separation of charged species that migrate in an applied electric field. Micellar Electrokinetic Chromatography describes an elegantly simple means of applying this technique for the separation of neutral species. Simply put, if a charged micelle can be made to remain more or less stationary in the electroosmotically flowing buffer, then neutral species will be separated based on differential partitioning to the micelle! This development opened entire new fields of separations.

Liquid chromatography uses organic solvents as components of the mobile phase. Driving forces for reduction of solvent use include environmental concerns and simply the economics of purchasing. Microscale High-performance Liquid Chromatography and the Evolution of Capillary Electrochromatography describes the miniaturization of the technique. Other advantages besides solvent savings exist as well, and the technique will slowly move in this direction.

The chemistry of the interaction of the solute with the mobile and stationary phases is how these elegant separations are developed. Normal-phase Liquid Chromatography uses a polar stationary phase and nonpolar liquid mobile phases for the separation of polar solutes. While this was the first method described by Tswett, usage of this method has dwindled but it is still a very powerful separation technique.

Reversed Phase Liquid Chromatography is by far the most practiced liquid separation method. The name arose from the reversal in elution order of most solutes compared to normal phase separations, and here a nonpolar stationary phase is used with polar mobile phases, typically water with an added polar organic solvent. Reversed-phase liquid chromatography is the workhorse method of the pharmaceutical industry.

The design of selective stationary phases is what allows the rapid, efficient separations that are achievable today. Silica Gel and its Derivatization for Liquid Chromatography describes how these phases are prepared, and offers challenges for better design of robust, reproducible phases.

While most analysts think of mobile phases as either gases or liquids, an almost 40-year-old technique exists using a mobile phase of a fluid taken above its critical point. Supercritical Fluid Chromatography describes this method, and shows the advantages offered when a fluid (mobile phase) has the solvating power of liquids, and diffusion coefficients closer to gases.

While column chromatography is a very powerful and often practiced method, one of its major limitations is that it is a "serial" technique. That is, one sample at a time is all that can be analyzed. Thin-layer Chromatography describes a liquid phase separation method performed on a flat plate, so that parallel "lanes" are possible, and separations can be run in parallel. While offering far lower resolving power than column methods, this is still a very heavily practiced method for the separation of simple mixtures, or for screening large numbers of samples.

Liquid chromatography is used for more than chemical analysis. The technique can be performed on both laboratory preparative scales and on industrial scales. Here the goal is throughput, the production of the greatest amount of pure material in the shortest time, and while the fundamentals of the separation process are essentially the same, the goal mandates that the operational aspects are quite different. Usually the sample (feed) is grossly overloaded onto the column, and the technique is referred to as nonlinear chromatography. Since an interfacial partitioning process is the most used mechanism of separation, the experiment can also be turned around, and the chromatography column can be used to measure these partitioning processes. Both thermodynamic and kinetic information can be obtained from a chromatography column.
Still, it is chemical analysis that drives further development of this technique. We will learn to better control the separation, we will learn to do it faster and with better limits of detection, but I doubt if we deviate much from the description of Tswett!
Affinity Chromatography

David S. Hage
University of Nebraska, Lincoln, NE, USA

1 Introduction

1.1 Definition and Overview of Affinity Chromatography

Affinity chromatography is a type of liquid chromatography that makes use of biological-like interactions for the separation and specific analysis of sample components. This article discusses the basic principles behind the theory and use of this method. Various factors that are important in the development of an affinity chromatographic system are considered, such as the choice of affinity ligand, support material, immobilization method, and elution conditions. A survey of the different types of affinity chromatography is also presented; this includes bioaffinity chromatography, immunoaffinity chromatography, dye-ligand affinity chromatography, immobilized metal affinity chromatography, and analytical affinity chromatography. In addition, some areas of expected future growth are considered, such as the use of molecular imprints or aptamers as ligands in affinity columns, and the coupling of affinity chromatography with other analytical techniques.

1.2 History of Affinity Chromatography

The first reported use of affinity chromatography is generally recognized as having been in 1910, when Starkenstein used an insoluble starch support to purify the enzyme α-amylase. There was some speculation in the mid-1920s about the value of using “fixed partners”, or affinity ligands, as a general scheme for the isolation of biologically active compounds, but there was little activity in this field for several decades after Starkenstein’s work. In 1951, Campbell et al. were the first to use artificially immobilized ligands in an affinity column, when they attached antigens to diazotized p-aminobenzyl cellulose for the purification of antibodies. After this work came several other applications, including reports...
LIQUID CHROMATOGRAPHY

on the use of affinity chromatography for the purification of tyrosinase, flavokinase, and avidin.

However, affinity chromatography did not see widespread use until the late 1960s. It was during this time period that there were several important developments that led to a greater flexibility and ease of use for affinity methods. One of these breakthroughs involved the introduction of better supports for affinity chromatography, such as beaded agarose. Another development that came about at this time was a report on the CNBr method for coupling proteins and other ligands to affinity supports through primary amine groups. Both of these advances were used in 1968 by Cuatrecasas, Wilchek, and Anfinsen to produce what are now considered the first “modern” affinity chromatographic separations.

Beginning in the 1970s, affinity chromatography saw rapid growth as a purification tool for biochemicals, but most of this work continued to employ soft gels like agarose for the affinity support. These gels tended to limit the usefulness of affinity chromatography as an analytical tool because of their ability to work at only relatively low flow-rates and operating pressures which, in turn, resulted in fairly long run times. More rapid separations were made possible by the development of alternative supports, such as the diol-bonded silica matrix reported in 1976 by Regnier and Noel. These newer materials could withstand the same pressures and flow-rates as used in high-performance liquid chromatography (HPLC) but still provided a surface that could be modified for ligand attachment and that provided low nonspecific binding for most biological compounds.

In 1978, Ohlson et al. combined these HPLC-compatible materials with affinity ligands to produce a method known as high-performance affinity chromatography (HPAC). It was this approach that now made it more feasible to use affinity chromatography as an analytical tool for the characterization of biological and non-biological samples.

2 THEORY OF AFFINITY CHROMATOGRAPHY

The most common method used for performing affinity chromatography is a step-wise elution scheme, as shown in Figure 1. In this approach, a sample containing the compound of interest is injected onto the affinity column in the presence of a mobile phase that has the right pH, ionic strength, and solvent composition for solute-ligand binding. This solvent, which represents the weak mobile phase of the affinity column, is called the application buffer. As the sample passes through the column in the application buffer, compounds which are complementary to the affinity ligand will bind. However, owing to the high selectivity of this interaction, other solutes in the sample will tend to elute from the column nonretained. After all nonretained components have been washed from the column, the retained solutes are then eluted by applying a solvent that displaces them from the column or that promotes dissociation of the solute–ligand complex. This solvent, which represents the strong mobile phase for the column, is known as the elution buffer. As the solutes of

![Figure 1](attachment:image.png)
interest elute from the column, they are either measured directly or collected for later use. The application buffer is then reapplied to the system and the column is allowed to regenerate prior to the next sample injection.\(^{(5,10)}\)

A number of factors are important in determining the retention and elution of a compound in an affinity column. These factors include the strength of the solute–ligand interaction, the amount of immobilized ligand present in the column, and the kinetics of solute–ligand association and dissociation. In the case where a solute (A) has single-site binding to a ligand (L), Equations (1–3) can be used to describe the interactions between the solute and ligand in an affinity column.

\[
A + L \overset{k_a}{\rightleftharpoons} A - L \tag{1} \\
K_a = \frac{k_a}{k_d} \tag{2} \\
= \frac{[A - L]}{[A][L]} \tag{3}
\]

In these relationships, \(K_a\) is the association equilibrium constant for the binding of A with L, \(A - L\) is the resulting solute–ligand complex, \([A]\) is the mobile phase concentration of A at equilibrium, and \([L]\) or \([A - L]\) represent the surface concentrations of the ligand or solute–ligand complex, respectively. The term \(k_a\) is the second-order association rate constant for solute–ligand binding and \(k_d\) is the first-order dissociation rate constant for the solute–ligand complex. At equilibrium, the retention of solute in the above system can be described by Equations (4) and (5).

\[
k = \frac{K_a m_L}{V_M} = \left(\frac{t_R}{t_M} - 1\right) \tag{4} \\
\]

where \(k\) is the retention factor for the injected solute, \(t_R\) is the solute’s retention time, and \(t_M\) is the void time of column.\(^{(10,23)}\) The term \(m_L\) represents the moles of active ligand in column and \(V_M\) is the column void volume.

Equations (4) and (5) indicate that the retention factor for a solute, or its retention time, will depend on both the strength of solute–ligand binding (i.e. the association equilibrium constant, \(K_a\)), and the amount of ligand in the column (i.e. \(m_L/V_M\)). This retention factor is often very large in the presence of the application buffers that are used in affinity chromatography. For instance, affinity columns that contain polyclonal antibodies as ligands (which generally have \(K_a\) values in the range of \(10^8 – 10^{10}\) M\(^{-1}\)) can give rise to retention factors of \(10^3\) or greater under physiological conditions.\(^{(10)}\) The only way in which solutes can be eluted from these columns in a reasonable amount of time is to lower the effective value of \(K_a\) for solute–ligand binding; in fact, this is the main role of the elution buffer for an affinity column.

Although the step gradient, or “on/off”, elution mode shown in Figure 1 is the most common way of performing affinity chromatography, it is also possible to carry out affinity methods by using isocratic elution. This second approach can be employed if the value of a solute’s association equilibrium constant (and retention factor) for the column are sufficiently small to allow elution on the minute-to-hour time scale. Fast association and dissociation kinetics are also desirable in this mode in order to allow a large number of solute–ligand interactions to occur as an analyte travels through the column, thus producing good plate heights and narrow peaks. This approach, sometimes called weak-affinity chromatography, is fairly easy to perform if a solute’s \(K_a\) value is less than or equal to \(10^4\) M\(^{-1}\), and has even been employed on some systems with association constants up to \(10^6\) M\(^{-1}\).\(^{(24–26)}\)

### 3 BASIC COMPONENTS OF AFFINITY SYSTEMS

#### 3.1 Affinity Ligands

The key factor in determining the success of any affinity separation is the type of ligand that is used within the column. A number of ligands that are commonly used in affinity chromatography are listed in Table 1. Many of these ligands are of biological origin, but a wide range of natural and synthetic molecules of nonbiological origin can also be used. However, all of these compounds can be placed into one of two categories: (1) high-specificity ligands and (2) general, or group specific, ligands.\(^{(5,10)}\)

The term high-specificity ligands refers to compounds which bind to only one or a few closely related molecules. This type of ligand is used in chromatographic systems where the goal is to analyze or purify a specific solute. Typical high-specificity ligands include antibodies (for binding antigens), substrates or inhibitors (for separating enzymes), and single-stranded nucleic acids (for the retention of a complementary sequence). As this list suggests, most high-specificity ligands tend to be biological compounds. These ligands also tend to have relatively large association constants for solutes and are generally eluted by a step gradient.

General, or group-specific, ligands are compounds that bind to a family or class of related molecules. These ligands are used in methods where the goal is to isolate a class of structurally similar solutes. General ligands can be of either biological or non-biological origin. Examples given in Table 1 include proteins A and G, lectins, boronates, triazine dyes, and immobilized metal chelates.
### Table 1: Common ligands used in affinity chromatography

<table>
<thead>

<td>Metal-binding amino acids, peptides, and proteins</td>
</tr>
</tbody>
</table>

Many of the compounds have weaker binding for solutes than that seen with high-specificity ligands; however, there are exceptions to this. For example, protein A has an equilibrium association of over $10^8 \text{ M}^{-1}$ for some types of antibodies. Also, some molecules which are usually considered to be high-specificity ligands, such as antibodies, can be used to retain an entire class of solutes if they recognize a feature that is common to all of the desired analytes.

### 3.2 Support Materials

Another important factor to consider in affinity chromatography is the material used to hold the ligand within the column. Table 2 lists some examples of common supports found in affinity columns. Ideally, this support material should have low nonspecific binding for sample components but should be easy to modify for ligand attachment. This material should also be stable under the flow-rate, pressure, and solvent conditions to be employed in the analysis or purification of samples. In addition, the support should be readily available and simple to use in method development.
Depending on what type of support material is being used, affinity chromatography can be characterized as either a low- or high-performance technique. In low-performance (or column) affinity chromatography, the support is usually a large-diameter, nonrigid gel. Many of the carbohydrate-based supports and synthetic organic materials listed in Table 2 fall within this category. An example of a separation based on low-performance affinity chromatography is shown in Figure 2. The low back-pressure of these supports means that they can often be operated under gravity flow or with a peristaltic pump. This makes these gels relatively simple and inexpensive to use for affinity purifications. Disadvantages of these materials include their slow mass transfer properties and their limited stability at high flow-rates and pressures. These factors limit the usefulness of these supports in analytical applications, where both rapid and efficient separations are often desired.\(^5\),\(^10\)

In HPAC, the support consists of small, rigid particles capable of withstanding the high flow-rates and/or pressures that are characteristic of HPLC.\(^5\),\(^10\),\(^22\) Examples of affinity supports that are suitable for work under these conditions include modified silica or glass, azalactone beads, and hydroxylated polystyrene media. The mechanical stability and efficiency of these supports allows them to be used with standard HPLC equipment. Although the need for more sophisticated instrumentation does make HPAC more expensive to perform than low-performance affinity chromatography, the better speed and precision of this technique makes it the method of choice for analytical applications.\(^5\),\(^10\),\(^11\) such as that shown in Figure 3.

(Reprinted from P. Brodelius, K. Mosbach, 'Separation of the Isoenzymes of Lactate Dehydrogenase by Affinity Chromatography using an Immobilized AMP-analogue', *FEBS Lett.*, 35, 223–226, Copyright (1973), with permission from Elsevier Science.)

**Figure 3** High-performance affinity chromatographic separation of concanavalin A (peak 2) from bovine serum albumin (peak 1) on an immobilized glucosamine column. The concanavalin A was eluted by applying at the arrow an elution buffer that contained methyl-\(\alpha\)-D-mannopyranoside. (Reprinted from R.R. Walters, 'High-performance Affinity Chromatography', *Trends Anal. Chem.*, 2, 282–285, Copyright (1983), with permission from Elsevier Science.)

### 3.3 Immobilization Methods

A third item to consider in using affinity chromatography is the way in which the ligand is attached to the
coupling the ligand through functional groups that occur in only a few places in its structure or by using a support with a low density of activated sites. Improper orientation can also lead to a loss in ligand activity but can be avoided by coupling the ligand through groups that are distant from its active region. If the actual location of the ligand's active site is not known or if no appropriate functional groups are available, it is sometimes possible to minimize this problem by empirically varying the procedure or conditions used for ligand attachment. Steric hindrance refers to the loss of ligand activity due to the presence of a nearby support or neighboring ligand molecules. Steric hindrance produced by neighboring ligands can be minimized by using a low ligand coverage, while steric hindrance produced by the support can be reduced by adding a spacer arm, or tether, between the ligand and supporting material. The presence of a spacer arm is particularly important when using small ligands for the retention of large analytes. Examples of common spacer arms used in affinity chromatography include 6-aminocaproic acid, diaminopropylamine, 1,6-diaminohexane, ethylenediamine and succinic anhydride.

### 3.4 Application and Elution Conditions

The application buffer is another parameter that must be considered in the use of an affinity column. Most application buffers in affinity chromatography are solvents that mimic the pH, ionic strength and polarity experienced by the solute and ligand in their natural environment. Any cofactors or metal ions required for solute–ligand binding should also be present in this solvent. Under these conditions, the solute will probably have its highest association constant for the ligand and its highest degree of retention on the column. The proper choice of the application buffer can also help to minimize any nonspecific binding due to undesired sample components. For example, coulombic interactions between
solute and the support can often be decreased by altering the ionic strength and pH of the application buffer. In addition, surfactants and blocking agents may be added to the buffer to prevent nonspecific retention of solutes on the support or affinity ligand.

The activity of the immobilized ligand should be considered in determining how much sample can be applied to the affinity column with each use. A rough indication of the maximum possible column binding capacity can be made by assaying the total amount of ligand present or by actually measuring the ligand’s binding activity. With some affinity systems, it is possible to see a large amount of nonretained solute during the application step even when the amount of injected sample is significantly less than known column binding capacity. This phenomenon, known as the split-peak effect, is caused by the presence of slow adsorption and/or mass transfer kinetics within the column (see Figure 5). This effect has been reported with many types of affinity ligands, but tends to occur with high-performance supports because of the more rapid flow-rates often used with these materials. Ways in which this effect can be minimized include reducing the flow-rate used for sample injection, increasing the column size, or placing a more efficient support within the column. In some cases, changing the immobilization method may help by providing a ligand with more rapid binding kinetics.

Figure 5 Nonretained (or free) fractions observed in split-peak measurements for the injection of rabbit immunoglobulin G onto a protein G affinity column at various sample application flow-rates. The top chromatogram shows the elution of rabbit immunoglobulin G on a column containing only diol-bonded silica, which has no binding for this analyte. (Reprinted from J.G. Rollag, D.S. Hage, J. Chromatogr. A., 795, 185–198, Copyright (1998), with permission from Elsevier Science.)

The conditions used for removal of retained solutes is another item that should be considered in the design of an effective affinity separation. Just as the application conditions are selected to maximize specific solute–ligand interactions, the elution conditions are chosen to promote fast or gentle removal of solute from the column. The elution buffer used in affinity chromatography can be either a solvent that produces weak solute–ligand binding (i.e., a small association equilibrium constant) or a solvent that decreases the extent of this binding by using a competing agent that displaces solute from the column. These two approaches are known as nonspecific elution and biospecific elution, respectively.

Biospecific elution is the gentler of these two elution methods since it is carried out under essentially the same solvent conditions as are used for sample application. This makes this approach attractive for purification work, where a high recovery of active solute is desired. Biospecific elution may be performed either by adding an agent to the eluting solvent that competes with the ligand for solute (i.e., normal role elution) or by adding an agent that competes with solute for ligand-binding sites (i.e., reversed-role elution). In both cases, retained solutes are eventually eluted from the column by displacement and mass action. The main advantage of biospecific elution is its ability to gently remove analyte from the column. The main disadvantages are the slow elution times and broad solute peaks that are typically produced by this approach. Other limitations in purification work include the need to remove the competing agent from the final fraction of eluted solute and, in analytical applications, the need to use a competing agent that does not produce a large background signal under the conditions used for analyte detection.

In nonspecific elution, the solute is eluted by changing the column conditions in order to weaken the interactions between any retained compounds and the immobilized ligand. This can be done by changing the pH, ionic strength, or polarity of the mobile phase. The addition of denaturing or chaotropic agents to the running buffer can also be used. This results in an alteration in the structure of the solute or ligand, leading to a lower association equilibrium constant and lower solute retention. Nonspecific elution tends to be much faster than biospecific elution in removing analytes from affinity columns. This results in sharper peaks, which in turn produces lower limits of detection and shorter analysis times. For these reasons, nonspecific elution is commonly used in analytical applications of affinity chromatography. This elution method can also be used in purifying solutes, but there is a greater risk of solute denaturation with this approach than there is with biospecific elution. Furthermore, care must be taken in nonspecific elution to avoid using conditions that are too harsh for the
column. If this is not considered, it may result in long column regeneration times or an irreversible loss of ligand activity.

4 TYPES OF AFFINITY CHROMATOGRAPHY

4.1 Bioaffinity Chromatography

Bioaffinity chromatography, also known as biospecific adsorption, is a name that is used to describe affinity methods that use a biological molecule as the affinity ligand. This was the first type of affinity chromatography that was developed and continues to represent the most diverse category of this technique. As stated earlier, the first use of bioaffinity chromatography was in 1910 when Starkenstein purified α-amylase using insoluble starch (a substrate for this enzyme) as both the support and affinity ligand. Further examples of ligands that are used in bioaffinity chromatography are provided in Table 1.

The use of bioaffinity chromatography for enzyme purification, as originally reported by Starkenstein, continues to be an important and common use of this method. The importance of this field is illustrated by a review which cites several hundred applications in this area alone. An example of an enzyme separation performed by bioaffinity chromatography is shown in Figure 2. Ligands that can be used for this purpose include enzyme inhibitors, coenzymes, substrates, and cofactors. For instance, nucleotide mono-, di-, and triphosphates can be used for the purification of various kinase enzymes, NAD has been used to isolate dehydrogenases, pyridoxal phosphate has been employed for the purification of tyrosine and aspartate aminotransferases, and RNA or DNA has been used for the collection of polymerases and nucleases. Antibodies that specifically bind to certain enzymes are also commonly used in such purification schemes.

Lectins represent a class of general ligands that are common in bioaffinity chromatography. The term lectin affinity chromatography is sometimes used to refer to the resulting separation method. Lectins are non-immune system proteins, generally of plant origin, that have the ability to recognize and bind certain types of carbohydrate residues. Some of the most common lectins that are used in affinity chromatography include concanavalin A (which binds to α-D-mannose and α-D-glucose residues), wheat germ agglutinin (which binds to D-N-acetylglucosamines) and jacalin (which binds to α-D-galactose residues). Other lectins that are also used are listed in Table 4. These ligands are valuable in the separation of many carbohydrate-containing compounds, such as polysaccharides, glycoproteins (e.g. immunoglobulins or cell membrane proteins), glycolipids and other types of glycoconjugates.

Another useful class of bioaffinity ligands are antibody-binding proteins. Two common examples of these are protein A, a bacterial cell wall protein from Staphylococcus aureus, and protein G, which is a cell wall protein from group G streptococci bacteria. These ligands have the ability to bind to the constant region of many types of immunoglobulins, or antibodies. This makes them useful in antibody purification, particularly when dealing with IgG-class antibodies. Protein A and protein G have their strongest binding to immunoglobulins at or near neutral pH but readily dissociate from these solutes when placed into a lower pH buffer. These two ligands differ in their ability to bind to antibodies from different species and classes. Recombinant versions of both protein A and protein G are available commercially along with a recombinant fusion protein, known as protein A/G, that blends the binding activities of these two ligands.

Other examples of antibody-binding proteins include protein B and mannan-binding protein. Protein B is a b antigen protein found on the surface of group A streptococci bacteria. It is useful in binding to several types of IgA-class antibodies, such as human IgA1, IgA2 and secretory IgA. However, it does not bind to mouse IgA or IgAs from many other types of mammals. Mannan-binding protein is found in the serum of various mammals and has been found to bind IgM-class antibodies in mouse ascites fluid, making it of potential use for the isolation of IgM monoclonal antibodies. The binding of antibodies to mannan-binding protein is calcium-dependent and the elution of bound IgM can be obtained by incorporating ethylene diamine tetracetic acid (EDTA) as a calcium-complexing agent into the mobile phase.

Nucleic acids and polynucleotides can act as either general or specific ligands in bioaffinity chromatography.
For instance, as high-specificity ligands they can be used to purify DNA/RNA-binding enzymes and proteins or to isolate nucleic acids that contain a sequence which is complementary to the ligand. As a group-specific ligand, an immobilized nucleic acid can be used to purify solutes that share a common nucleotide sequence. An example is the use of immobilized oligo(dT) for the isolation of nucleic acids containing poly(A) sequences. As mentioned earlier, another example of a general nucleic acid ligand is the use of nucleotide mono-, di-, and triphosphates for the purification of kinase enzymes.4

4.2 Immunoaffinity Chromatography

Immunoaffinity chromatography (IAC) is a special category of bioaffinity chromatography in which the ligand that is used is an antibody or antibody-related reagent.

Other methods that are sometimes included under the heading of IAC are those that use immobilized antigens or antibody-binding proteins for antibody purification. The first known use of IAC was the work described earlier by Campbell et al. in 1951. Many current applications are still based on the use of low-performance supports, particularly agarose. However, recent work has also been performed using derivatized silica, glass, and perfusion media. The use of these supports along with an antibody or antigen ligand is referred to as high-performance immunoaffinity chromatography (HPIAC).

The high selectivity of antibody–antigen interactions and the ability to produce antibodies against a wide range of solutes has made IAC a popular tool for biological purification and analysis. There are now literally hundreds to thousands of examples of immunoaffinity methods that have been developed for the isolation of antibodies, hormones, peptides, enzymes, recombinant proteins, receptors, viruses, and subcellular components. The high association equilibrium constants of many antibodies requires that nonspecific elution be used with most immunoaffinity columns. However, isocratic elution methods can also be used with low-affinity antibody systems.

The use of IAC in analytical methods has also received a great deal of attention in recent years. Table 5 summarizes some strategies that can be employed in these analyses and gives some examples of representative applications. The simplest format for using IAC in compound analysis involves the traditional “on/off” or step-gradient mode of affinity chromatography (see Figure 1). The advantages of using this approach in analytical applications, particularly when performed by HPIAC, include its relative simplicity, good precision, and potential for fast sample analysis. One requirement of the direct detection mode is that there must be some way to monitor the analyte as it leaves the column. For protein solutes, UV absorbance measurements at 210–215 nm or 280 nm are most commonly used. In some cases minor sample components have been monitored by using pre-column derivatization to place easy-to-detect labels (such as fluorescent tags) on sample solutes prior to injection. Another alternative is to collect fractions of the column eluent and later analyze these by a separate technique, such as an immunoassay or assay for biological activity. Immunoextraction is another approach by which immunoaffinity columns can be used for solute detection. In this method, an immunoaffinity column is used for the removal of a specific solute or group of solutes from a sample prior to determination by a second analytical method. This employs the same general operating scheme as shown in Figure 1, but now involves combining the immunoaffinity column either off-line or on-line with some other method for the actual quantitation of analytes. Off-line methods are generally the easiest and most common way for combining immunoaffinity columns with other analytical techniques.

Immunoextraction generally involves manual sample preparation does limit the potential speed and precision of this approach. To overcome this problem, a large number of recent reports have examined the use of on-line immunoextraction methods. The direct coupling of immunoextraction with HPLC has been of particular interest, but some methods have also been reported that involve the coupling of on-line immunoextraction with GC or capillary electrophoresis. A typical column switching scheme for performing on-line immunoextraction with reversed-phase liquid chromatography (RPLC) is shown in Figure 6. The general format for this type of system involves injecting the sample onto the immunoaffinity extraction column, with the nonretained components being allowed to go to a waste container. The immunoaffinity column is then switched on-line with a RPLC column and an elution buffer is applied to the immunoaffinity support to dissociate any retained analyte. As these analytes elute, they are captured and...

reconcentrated at the head of the RPLC column. After all solutes have left the immunoaffinity column, this column is then switched back off-line and regenerated by passing through the initial application buffer. Meanwhile, the RPLC column is developed with either an isocratic or gradient elution scheme involving the application of a mobile phase with an increased organic modifier content. As the solutes elute through the RPLC columns, they are then monitored and quantitated at an on-line detector. (11)

A third area that has received increasing attention in recent years has been the use of IAC to perform various types of chromatographic (or flow-injection) immunoassays. (11,48) This is particularly valuable in determining trace analytes that, by themselves, may not produce a readily detectable signal. The competitive binding assay is the most common format that has been used in performing these immunoassays. One way this can be done is to mix the sample with a labeled analyte analog (i.e. the “label”) and simultaneously inject these onto an immunoaffinity column that contains a relatively small amount of antibody; this method is known as a simultaneous injection competitive binding immunoassay. An alternative format, known as a sequential injection competitive binding immunoassay, involves the application of only sample to the immunoaffinity column, followed later by a separate injection of the label (see Figure 7a). In either case, the analyte competes with the injected label for the antibody binding sites in the column, thus making the amount of label that elutes in either the retained or nonretained fractions an indirect measure of how much analyte was present in the original sample.

Sandwich immunoassays and one-site immunometric assays have also been performed as part of immunoaffinity systems. (11,48) In the sandwich immunoassay (Figure 7b), two different types of antibodies are used that each bind to the analyte of interest. The first of these two antibodies is attached to a solid-phase support and is
used to extract the analyte from samples. The second antibody contains an easily measured tag and is added in solution to the analyte either before or after this extraction; this second antibody serves to place a label onto the analyte, thus allowing the amount of analyte on the immunoaffinity support to be quantitated. In the one-site immunometric assay, the sample is first incubated with a known excess of labeled antibodies or Fab fragments that are specific for the analyte of interest. After binding between the sample analyte and antibodies has occurred, this mixture is then applied to a column that contains an immobilized analog of the analyte. This column serves to extract any antibodies or Fab fragments that are not bound to sample analyte. Meanwhile, those antibodies or Fab fragments that are bound to sample analyte will pass through the column in the nonretained peak. Detection is then performed by looking at the size of the nonretained peak for the labeled antibodies/Fab fragments.

Yet another way in which immunoaffinity columns can be used is for monitoring the elution of specific solutes from other chromatographic columns, a technique known as post-column immunodetection. This involves the use of a post-column reactor and an immobilized antibody or antigen column attached to the exit of an analytical HPLC column. This can be performed by either using the on/off direct detection mode of IAC or chromatographic immunoassay formats based on one-site immunometric assays, sandwich immunoassays or competitive-binding immunoassays. The one-site immunometric assay is the most common format for immunodetection. The basic operation involves taking the analytical HPLC column eluent and combining this with a solution of labeled antibodies or Fab fragments that will bind the analyte of interest. The column eluent and antibody or Fab mixture is then allowed to react in a mixing coil and passed through an immunodetection column that contains an immobilized analog of the analyte. The antibodies or Fab fragments that are bound to the analyte will pass through this column and onto the detector, where they will provide a signal that is proportional to the amount of bound analyte. If desired, the immunodetection column can later be washed with an eluting solvent to dissociate the retained antibodies or Fab fragments; but a sufficiently high binding capacity is generally used so that a reasonably large amount of analytical column eluent can be analyzed before the immunodetection column must be regenerated.
4.3 Dye-ligand Affinity Chromatography

Another category of affinity chromatography is the technique known as dye-ligand affinity chromatography. The first use of dye-ligand affinity chromatography was described in 1974. Since that time it has become an extremely popular tool for enzyme and protein purification, with over 500 such compounds having been isolated by this technique. In this method, a synthetic dye (like a triazine or triphenylmethane compound) is used as the immobilized ligand (see Figure 8). These dyes bind to the active site of a protein or enzyme by mimicking the structure of a substrate or cofactor for that biomolecule. The most common dye used for this purpose is Cibacron Blue F3G-A. Some other examples of dyes that are used as ligands in affinity chromatography include Procion Blue MX-3G or MX-R, Procion Red HE-3B, thymol blue and phenol red.

The cibacron and procion dyes all have a chlorotriazine ring but have different side groups attached to this ring. For Cibacron Blue F3G-A, one of these side groups is an anthraquinone that reacts with enzymes that have a binding site for NAD, NADP or ATP. This property makes this dye useful as a ligand for the purification of dehydrogenases, kinases, and other enzymes that require such cofactors. However, this same dye can also be used for a wide range of other enzymes and proteins. Examples include albumin, α-fetoprotein, CoA-dependent enzymes, hydrolases, immunoglobulin G, lipoproteins, nucleases, polymerases, synthetases and transferases. The other dyes used in dye-ligand affinity chromatography have slightly different specificities, but can similarly be used for the purification of a variety of enzymatic and nonenzymatic proteins.

4.4 Immobilized Metal Ion Affinity Chromatography

In immobilized metal ion affinity chromatography (IMAC), or metal chelate affinity chromatography, the affinity ligand is a metal ion which is complexed with an immobilized chelating agent. This type of affinity chromatography was first described by J. Porath and co-workers in 1975. It was initially used to separate proteins and peptides that contained amino acids with electron donor groups (such as histidine, tryptophan, or cysteine) with the proteins and peptides being retained owing to interactions between their amino acids and the immobilized metal chelate. Since its discovery, a number of peptides, proteins, and amino acids have been purified by this method. An example of one such separation is shown in Figure 9.

Selectivity in IMAC is determined by the chelating group and the type of metal ion that is used to make up the affinity ligand. Iminodiacetic acid is the most common chelating agent employed. Other ligands that are used in IMAC include carboxymethyl-aspartic acid, tris-carboxymethylhexylenediamine, tris(2-aminoethyl)amine and dipicolylamine. Metal ions used with these chelating groups include Cu²⁺, Zn²⁺, Ni²⁺, Co²⁺, and Fe³⁺. In general, the stronger that the interaction is between the metal ion and the chelating group, the weaker the observed retention will be between the same immobilized metal and an injected protein or peptide.

4.5 Analytical Affinity Chromatography

Besides its use in separating and quantitating sample components, affinity chromatography can also be employed as a tool for studying solute–ligand interactions. This application of affinity chromatography is called analytical, or quantitative, affinity chromatography. Using this technique, information can be acquired regarding the equilibrium and rate constants for biological interactions, as well as the number and types of binding sites that are involved in these interactions.

Information on the equilibrium constants for a solute–ligand system can be obtained by using either the method
Figure 9 Injection of a mixture of ribonuclease A (1), transferrin (2), and carbonic anhydrase (3) onto an immobilized iminodiacetic acid column in (a) the presence of Zn$^{2+}$ complexed to the column and (b) in the absence of Zn$^{2+}$. (Reprinted from Y. Kato, K. Nakamura, T. Hashimoto, ‘High-performance Metal Chelate Affinity Chromatography of Proteins’, J. Chromatogr., 354, 511–517, Copyright (1986), with permission from Elsevier Science.)

of zonal elution or frontal analysis. Zonal elution involves the injection of a small amount of solute onto an affinity column in the presence of a mobile phase that contains a known concentration of a competing agent. The equilibrium constants for binding of the ligand with the solute (and competing agent) can then be obtained by examining how the solute’s retention changes with competing-agent concentration. A typical zonal elution experiment is shown in Figure 10. This technique was first used to study biological interactions by Andrews et al. in 1974 and by Dunn and Chaiken in 1975. Since that time it has been used to examine a number of systems, such as enzyme–inhibitor binding, protein–protein interactions, and drug–protein binding.

Frontal analysis is performed by continuously applying a known concentration of solute to an affinity column at a fixed flow-rate. The moles of analyte required to reach the mean point of the resulting breakthrough curve is then measured and used to determine the equilibrium constant for solute–ligand binding. This method was used first by Kasai and Ishii in 1975 to examine the interactions of trypsin with various peptide ligands. It has since been used in many other applications. One advantage of this approach over zonal elution is that it simultaneously provides information on both the equilibrium constants and the number of active sites involved in analyte–ligand binding. The main disadvantage of this method is the need for a larger quantity of solute than is required by zonal elution.

Figure 10 (a) Chromatograms and (b) relationship between the retention factor ($k$) and mobile phase additive concentration for zonal elution competitive binding experiments performed on an immobilized human serum albumin column using R-warfarin as the injected analyte and L-reverse triiodothyronine (L-rT$_3$) as a mobile phase additive. The mobile phase concentrations of L-rT$_3$ in (a) were (left-to-right) 1.90, 0.97, 0.49, 0.24 and 0µM. (Reprinted from B. Loun, D.S. Hage, ‘Characterization of Thyroxine–Albumin Binding Using High-performance Affinity Chromatography. II. Comparison of the Binding of Thyroxine, Triiodothyronine and Related Compounds at the Warfarin and Indole Sites of Human Serum Albumin’, J. Chromatogr. B, 665, 303–314, Copyright (1995), with permission from Elsevier Science.)
Information on the kinetics of solute–ligand interactions can also be obtained using affinity chromatography. A number of methods have been developed for this, including techniques based on band-broadening measurements, the split-peak effect, and peak decay analysis. These methods are generally more difficult to perform than equilibrium constant measurements but represent a powerful means of examining the rates of biological interactions. Systems that have been studied by these techniques include the binding of lectins with sugars, protein A or protein G with immunoglobulins, antibodies with antigens, and drugs or amino acids with human serum albumin.

4.6 Miscellaneous Ligands and Methods

Besides the specific methods already discussed, a number of other ligands and techniques are often placed under the category of affinity chromatography. For example, boronic acid and its derivatives represent a class of general ligands that are usually considered to be affinity ligands. At a pH of 8 or higher, these ligands have the ability to form covalent bonds with compounds that contain cis-diol groups in their structure. This makes these ligands useful for the purification and analysis of many compounds which contain sugar residues, such as polysaccharides, glycoproteins, ribonucleic acids, and catechol-related compounds.

Other methods that are related to affinity chromatography include hydrophobic interaction chromatography (HIC) and thiophilic adsorption. HIC is based on the interactions of proteins, peptides, and nucleic acids with short nonpolar chains on a support. This was first described in 1972 following work that examined the role of spacer arms on the nonspecific adsorption of affinity columns. Thiophilic adsorption, also known as covalent or chemisorption chromatography, makes use of immobilized thiol groups for solute retention. Applications of this method include the analysis of sulfhydryl-containing peptides or proteins and mercurated polynucleotides.

5 FUTURE DEVELOPMENTS

A clear trend that has been present since the beginning of affinity chromatography has been the search for new and improved ligands to use in this technique. It has already been shown how a variety of biological and nonbiological compounds have been employed in affinity separations. In the future it is anticipated that an even greater variety of affinity stationary phases will be developed. One group of promising candidates are the aptamers, which are polymers of 8–120 nucleotides that have well-defined sequences and three-dimensional structures. It has been shown that a large number of aptamers can be randomly generated in an oligonucleotide library and then those ligands which bind to a given target solute can be selectively enriched for use in chemical sensors or other applications. The result is a ligand that is stable, easy to prepare and that has a relatively high affinity for the solute of interest.

Another active area of new stationary phase development is in the field of molecular imprinting. In this case, the affinity ligand is actually part of the surface or internal structure of the support used in the affinity column. Molecular imprints are usually made by combining the analyte of interest with a series of monomers that contain side chains capable of forming various interactions with the analyte. As these interactions take place, the monomers are fixed in position about the analyte by initiating their polymerization (see Figure 11). After the polymerization has occurred, the support is ground into a powder, the retained analyte is released by applying an appropriate solvent, and the imprinted support is placed into a column for use. In this way, an affinity support is created that has a known specificity and binding/elution properties.

A second trend in affinity chromatography has been the increasing use of this method in tandem analytical techniques. For instance, Table 5 shows how IAC has already been combined, both on-line and off-line, with HPLC, GC and capillary electrophoresis. Similar interfaces have been developed for other ligands (e.g., protein A, protein G, and boronic acid), but these have not seen nearly as much use as immunoaffinity columns in tandem techniques. One role that an affinity column can play in such a tandem system is to selectively extract an analyte or group of analytes from a sample prior to study by a second analytical method. The affinity column can also be used as a type of sensor to selectively monitor a given agent as it appears in the other analytical technique. The enhanced specificity that results in the overall method is a key reason why tandem affinity systems are receiving a good deal of attention in areas such as pharmaceutical analysis, food testing, and environmental monitoring.

Biopolymers are biological macromolecules including peptides, proteins, nucleic acids, and polysaccharides whose physical and chemical properties differ considerably from those of small molecules. Biopolymer chromatography is a branch of liquid chromatography which is adapted to the specific requirements of biopolymers in order to obtain rapid and high-resolution chromatographic separations of these molecules. Because of the low diffusion coefficients of biopolymers, special stationary phase configurations and surface modifications are necessary to permit sufficiently fast mass transfer kinetics between the mobile and stationary phase. Exploiting different molecular properties of the biopolymers, such as size, charge, hydrophilicity, hydrophobicity, the ability to form complexes with metal ions, or biological function, the most popular liquid chromatographic modes for biopolymer separation are size-exclusion, ion-exchange, normal-phase, reversed-phase, ion-pair reversed-phase, metal-interaction, and affinity chromatography.

Because of their large size and the multitude of different functional groups present in biopolymers, more than one mechanism may be responsible for interaction with the stationary phase, resulting in enhanced selectivity due to mixed-mode interactions. Adsorption at multiple sites results in very steep elution isotherms as a function of the mobile phase solvent strength. Therefore, elution with a gradient of increasing solvent strength is usually applied in biopolymer chromatography. The choice of a suitable chromatographic environment is of special importance if
the native confirmation of a biopolymer, which is essential for its biological activity, is to be preserved for subsequent experiments. Generally, conditions that come close to the physiological environment are most appropriate.

The most important detection techniques for biopolymers are ultraviolet/visible absorbance detection, fluorescence detection, electrochemical detection, mass spectrometry, and low-angle laser light scattering photometry. Miniaturization and multidimensional separation together with mass spectrometric detection allow the routine separation and identification of femt mole–attomole amounts of hundreds to thousands of different biopolymers contained in complex mixtures of biological origin.

1 INTRODUCTION

Biopolymers are naturally occurring macromolecules, primarily peptides, proteins, nucleic acids, and polysaccharides, that represent essential constituents of all living organisms. Their molecular mass ranges from roughly 1000 to several million. Although biopolymers exhibit an immense structural and functional diversity, they share a common building principle where relatively few building blocks of different chemical structure are assembled into polymeric chains that constitute the three-dimensional structure of the biomacromolecule. Thus, an estimated number of $10^{11}$ naturally occurring proteins is built up by only 20 amino acids and the whole human genome comprising $3 \times 10^9$ nucleotides contains only four different nucleobases. The characterization and structural analysis of biopolymers is of utmost importance in all areas of biological sciences and represents the key to understanding their biological function.

Biopolymers are usually present in relatively complex mixtures, hence separation before structural investigation is obligatory. The two principal and most powerful methods to asses the composition of biological samples and to separate the individual components are liquid chromatography (LC) and electrophoresis. The extraordinary popularity of high-performance liquid chromatography (HPLC) for the separation and analysis of biopolymers can be attributed to a number of factors:

1. Excellent resolution can be achieved for both closely related and structurally disparate substances under a large variety of chromatographic conditions.
2. Chromatographic selectivity can be manipulated readily through changes in mobile phase composition and/or choice of a suitable stationary phase from a large number of commercially available stationary phases.
3. Even submicrogram amounts of biopolymers can be isolated with high recovery.
4. Rapid separation and quantitation can be carried out with high reproducibility and accuracy on a timescale ranging from a few seconds to hours.

In principle, the theory of LC for biopolymers is the same as that for small molecules (see Column Theory and Resolution in Liquid Chromatography). However, as the diffusion coefficient decreases with increasing solute molecular mass, 1–2 orders of magnitude can separate the diffusion rates of small and large molecules in the liquid phase (e.g., diffusion coefficient of $9 \times 10^{-6}$ versus $0.6 \times 10^{-6} \, \text{cm}^2 \, \text{s}^{-1}$ for alanine and hemoglobin in water, respectively). The slow diffusion characteristics of biopolymers are responsible for slow kinetics of adsorption/desorption at the stationary phase and secondary equilibria resulting in lower column efficiency relative to separations involving small molecules. On the other hand, the separation selectivity for biopolymers is often better than for small molecules allowing the application of gradient elution, which counterbalances the lower column efficiency and has the additional advantage of increasing the peak capacity (see Gradient Elution Chromatography).

In many cases, especially for proteins, the three-dimensional structure of a biopolymer is essential for its biological activity. Therefore, careful choice of the appropriate method and chromatographic conditions is necessary to preserve the three-dimensional structure during the chromatographic separation process if the separated material is to be used for subsequent investigations where biological activity is important. Generally, chromatographic conditions similar to the physiological environment, such as aqueous buffer solutions at neutral pH, are most appropriate for the preservation of biological activity. However, biopolymers in solution can have parts of the molecule as well as the whole molecule folded, resulting in a variety of different conformations. If the time required for interconversion of these various more or less folded species is comparable to the time of separation, the resulting peak profiles are quite wide and often misshapen, resulting in poor separation efficiency. Therefore, strongly denaturing conditions, e.g., extreme pH, high temperature, or organic solvents, help to improve the resolving power of chromatography as a result of higher chromatographic selectivity for unfolded or partially denatured forms than for the native form of biopolymers at the cost of loss of biological activity.

2 SEPARATION PRINCIPLES FOR BIOPOLYMERS

There are a great number of chromatographic methods available for the fractionation of biopolymers that are designed to sense differences in size, shape, flexibility,
charge, polarity, or biological function of the compounds to be separated.\(^{4}\) It has been appreciated that the so-called noninteractive modes of chromatographic separation do not exhibit the same level of resolution as the interactive modes.\(^{2}\) Consequently, the most successful separation techniques are those capable of selective interaction by probing the topography of biopolymers.

Size-exclusion chromatography (SEC) and slalom chromatography represent exceptional modes in that the separation of the sample components takes place without their interaction with the stationary phase and, therefore, they are called noninteractive modes of chromatography (Table 1). By contrast, the interactive modes are conveniently identified by the term of the particular interaction (Table 1). Thus, we distinguish between electrostatic interaction, where immobilized charges on the stationary phase interact with the charged biopolymer molecules, polar interaction, where permanent or induced dipoles interact with each other, and hydrophobic interaction, where the interaction is between hydrophobic moieties. Since charged, polar, and hydrophobic domains are all present on the surface of most biopolymers, these interactions are of general type. In metal interaction chromatography (MIC), biopolymers are retained by the semispecific complexation of an immobilized metal ion at the stationary phase. Involving electrostatic, polar, and dispersive interactions as well as steric factors of interaction at the same time, affinity chromatography (AC) exploits highly specific interactions characteristic of many biochemical systems.

Macromolecular solutes interact with the stationary phase in a different way from that of small molecules. Because of the large molecular dimensions of biopolymers, it can be expected that the geometry and distribution of charged, hydrophobic, polar, and complexing groups on their surface greatly influence the adsorption behavior. Several of such adsorption sites on the biopolymer surface make it highly probable that adsorption at the stationary phase will occur at multiple sites.\(^{5}\) This characteristic, unique to macromolecules, is responsible for extremely steep elution isotherms resulting in an enormously rapid change in solute retention with small changes in the elution strength of the mobile phase, a phenomenon often referred to as the ‘on–off’ model.\(^{4}\) According to this model, the solute initially sticks at the inlet of the column and at some critical solvent strength during a gradient run it is totally desorbed and rapidly elutes from the column (Figure 1).

#### 2.1 Size-exclusion and Slalom Chromatography

SEC separates biopolymers on the basis of their size and is different from the interactive modes of chromatography in that any interaction between the analytes and the stationary phase has to be prevented. The size-exclusion effect is based on the fact that the stationary phase particles have pores with a defined distribution of pore diameters. Large molecules of dimensions larger than

![Figure 1](image-url) Plots of the logarithmic retention factor versus the concentration of acetonitrile in the RPC (reversed-phase chromatography) of lysozyme (\(M_r\) 16951.5, solid lines) and nitrobenzene (\(M_r\) 123.11, dashed lines) on a PLRP-S macroporous, cross-linked polystyrene stationary phase from Polymer Laboratories. LIQUID CHROMATOGRAPHY

the pore diameter are totally excluded from the internal volume and leave the column first (Figure 2a). For small molecules, all pore diameters are large enough to allow penetration of the whole internal volume. Molecules of intermediate size have access only to a portion of the internal volume but will be excluded from the smaller pores. Thus, in SEC, analytes are separated by molecular size.

The upper molecular mass limit of SEC is determined by the maximum pore diameter of the packing material and the shape of the biomacromolecule. For instance, approximately 20% of the pore volume of a stationary phase with 10 nm average pore diameter is accessible for proteins with a molecular mass of 50 000 whereas 50% of the pore volume of a stationary phase with 50-nm pores is accessible for proteins with a molecular mass of around 500 000. The molecular size of linear polymers of random coil structure, such as nucleic acids or linear polysaccharides, is closely related to the molecular mass. Proteins, however, exist in an ordered tertiary structure, which is much denser than that of random coils. Consequently, they can penetrate more of the pore volume than random coiled biopolymers of commensurate molecular mass. In Table 2, the molecular masses and sizes of some biopolymers are summarized.

Slalom chromatography has been developed for the separation of large, double-stranded DNA molecules (>1000 base pairs) that behave like a flexible random coil in aqueous solution. When DNA molecules are applied to a column which is packed with hard and spherical beads, they are unfolded and extended owing to the laminar flow of solvent passing through the narrow openings between the closely packed particles. The separation is based on the fact that long DNA molecules (5000–50 000 base pairs) have to turn very fast during their passage through the narrow and tortuous channels between the packing particles (Figure 2b). The longer the DNA molecule, the more difficult it is to pass through the openings and, consequently, a separation according to size, where smaller DNA molecules elute first, is achieved. Important features of slalom chromatography are that DNA fragments do not interact with the column packing, that separation depends strongly on particle size and flow rate, and that the DNA fragments are totally excluded from the pores, and therefore pore size and pore volume are not important factors in determining the separation.

2.2 Ion-exchange Chromatography

Ion-exchange chromatography (IEC) separates molecules based on differences in their accessible surface charges (see Ion Chromatography). An ion-exchange stationary phase consists of positively charged (for anion exchange, see Figure 3a) or negatively charged (for cation exchange) functional groups immobilized on a suitable support material. The electrostatic interactions between the oppositely charged groups on the surface of the stationary phase and on the surface of the analytes are responsible for adsorption. Since biopolymers also contain nonpolar areas, relatively weak dispersive interactions with the stationary phase may provide additional retention.

Desorption takes place when the ionic strength of the mobile phase is increased by applying a gradient of increasing salt concentration. The salt concentration needed to displace the adsorbed biopolymers back into the mobile phase depends on the strength of the
electrostatic interactions between the stationary phase and the biopolymer.

Consequently, the retention behavior of biopolymers in IEC depends strongly on their charge characteristics. The total net charge and the actual distribution of charges within a biomacromolecule critically affect both adsorption and elution. Whereas the phosphodiester groups of nucleic acids are dissociated over a broad pH range (2–14), the pH of the mobile phase strongly influences the charge characteristics of peptides and proteins. Oligosaccharides can be ionized only at pH values higher than 12 owing to the weak acidity of the hydroxyl groups. In addition to affecting the charge distribution within the molecule, the pH can also have an effect on the three-dimensional conformation of a biomacromolecule. Because of these phenomena, the effect of pH on the chromatographic selectivity can be profound and difficult to predict and an empirical approach to evaluate an ion-exchange separation over a range of pH values is necessary. The advantage of the ion-exchange mechanism is that under suitable pH conditions, relatively few or no structural changes in the biopolymers occur because the interaction between the stationary phase and the analyte is weak apart from the electrostatic interactions which are directed and specific.

2.3 Normal-phase Chromatography

In normal-phase chromatography (NPC), the stationary phase is more polar than the mobile phase (see Normal-phase Liquid Chromatography). The intermolecular interactions governing retention and selectivity in this mode are polar in origin, encompassing both hydrogen bonding, the extent of which depends upon the Lewis acidity or basicity of the interacting molecules, and dipole–dipole interaction, which is dependent on the dipole moments and polarizabilities of the molecules. The polar surface of a normal-phase stationary phase can either be obtained by derivatizing a support material with a suitable polar functional group, or it can be the original support, as in the case of silica gel. The retention of polar analytes increases with increasing hydrophilicity of the stationary phase and with decreasing hydrophilicity of the mobile phase, typically mixtures of organic solvents.

2.4 Reversed-phase Chromatography

Reversed-phase chromatography (RPC) separates biopolymers on the basis of differences in their hydrophobic properties (see Reversed Phase Liquid Chromatography). The stationary phase in RPC is a very hydrophobic, nonpolar surface, whereas the mobile phase is polar, usually a mixture of water and organic solvents. The hydrophobic interaction results from a tendency of nonpolar molecules to interact with each other rather than with water, resulting in the distribution of a hydrophobic solute between the hydrophobic hydrocarbon chains of the stationary phase and the mobile phase (Figure 3b). Reducing the polarity of the mobile phase through increasing the concentration of an organic solvent allows the hydrophobically bound analytes to desorb from the stationary phase, causing elution from a reversed-phase column. Under the conditions of RPC, i.e. the employment of hydroorganic solvents in combination with a strongly hydrophobic surface, proteins often lose their three-dimensional shape and denature, resulting in loss of biological activity, which cannot always be restored by putting the protein in a more physiological environment after separation. Nevertheless, the high resolution capability of this technique is a result of higher chromatographic selectivity for unfolded or partially denatured forms than for the native forms of the proteins, which makes RPC an important tool for high-resolution analytical separations.

2.5 Ion-pair Reversed-phase Chromatography

Ion-pair reversed-phase chromatography (IPRPC) is traditionally seen as a special branch of RPC because stationary phases and elution conditions typical for RPC are used. However, from a mechanistic point of
LIQUID CHROMATOGRAPHY

2.6 Hydrophobic Interaction Chromatography

Hydrophobic interaction chromatography (HIC) separates biopolymers based on the hydrophobicity of their surface. Binding of biopolymers is induced by the addition of high salt concentration (1–5 mol L\(^{-1}\)) whereas elution is accomplished by lowering the salt concentration (Figure 4b). The organization of the water molecules surrounding the analytes and the binding surface is the driving force for hydrophobic adsorption. When a hydrophobic region of a biopolymer binds to the surface of a mildly hydrophobic stationary phase, hydrophilic water molecules are effectively released from surrounding the hydrophobic areas, causing a thermodynamically favorable change in entropy. Because hydrophobic interaction is driven by entropy, temperature can have a strong effect.

Compared with RPC, the surface of the stationary phase in HIC is less hydrophobic so that no organic solvent is necessary for desorption of the analytes. Therefore, the three-dimensional structure of biopolymers is usually preserved during a separation by HIC. Ammonium sulfate, by virtue of its good salt-out properties and high solubility in water, is the most common salt used for HIC. The salt concentration required for the induced hydrophobic interaction can be modulated by changing the hydrophobicity of the stationary phase. More hydrophobic phases require less salt for binding. If the bonded phase is too apolar, the analytes do not elute when the salt is removed.

2.7 Affinity Chromatography

AC is based on biospecific interactions between a ligand covalently bound to the chromatographic packing and a target biopolymer in the sample solution (see Affinity Chromatography). The technique is almost exclusively utilized to purify proteins, although there are a few applications with peptides and nucleic acids. The forces involved in biospecific interaction include the same electrostatic and hydrophobic interactions that cause nonspecific ion-exchange and hydrophobic binding. However, in the case of biospecific or affinity binding, the interacting groups are arranged on the two bonding molecules in a unique orientation. Moreover, hydrogen bonding also plays an important role. The two ligands thus fit together very much like a lock and key, with a high degree of specificity (Figure 5a). Elution from affinity media can be done under any conditions that disrupt the ligand–ligand interaction. The most common technique is to employ a shift to acidic pH (2–4), which induces dissociation because of protonation of acidic groups. Other elution techniques include the increase of ionic strength or the use of specific displacers such as the immobilized ligand or analog in free solution. Affinity elution is usually in the form of a step gradient.

2.8 Metal Interaction Chromatography

MIC is a method for the separation of biopolymers which are capable of complexing with an immobilized
transition metal ion on the surface of a suitable support. The metal ion (typically Cu$^{2+}$, Zn$^{2+}$, Ni$^{2+}$, Co$^{2+}$, or Fe$^{3+}$) is usually bound to the support by means of a chelating ligand (typically iminodiacetate) such that one or more coordination sites are available for interaction with ligands that are part of biopolymers (Figure 5b). Typical functional groups in biopolymers capable of complexation with transition metal ions are imidazole, amino, and thiol groups present in the amino acids histidine, lysine, and cysteine (with Cu$^{2+}$, Ni$^{2+}$), phosphate groups in nucleic acids (with Fe$^{3+}$), and vicinal diols present in saccharides (with Cu$^{2+}$). Elution of complexed biopolymers is accomplished with gradients of increasing salt concentration or, even more effective, with increasing gradients of competitive ligands such as imidazole or phosphate.

3 STATIONARY PHASES FOR BIOPOLYMER SEPARATION

The choice of a suitable stationary phase is one of the first decisions to be made in the design of a chromatographic separation for a biopolymer mixture. Initially, it was assumed that the pool of packing materials commercialized for the separation of low molecular mass analytes could be easily transferred to the separation of biopolymers. However, it soon became apparent that the handling of these substances in HPLC requires careful control of the morphology and the surface chemistry of the chromatographic packing material. The two major concerns that have to be taken into account with biopolymers are slow mass transfer because of the low diffusivities of biopolymers and multimodal interaction of biopolymers with the stationary phase. Usually it is advantageous to restrict the molecular interactions between analyte molecules and the stationary phase to one predominant interaction (single-mode interaction, Table 1), although other forces and mechanisms may play a role in determining the final separation (mixed-mode or multimode interaction). In many cases, however, these additional interactions are difficult to control and result in band broadening and asymmetric peak shapes.

For size-exclusion packing materials, the pore size distribution and a surface chemistry that prevents any interaction between the stationary phase and the analyte are the factors determining the success of separation. In the interactive modes of chromatography the driving forces of retention and selectivity are the molecular interactions between the analyte and the surface of the stationary phase. Additionally, the steric environment of the packing material affects the molecular interactions. The selection of an optimal pore size for a particular sorbent is made on the basis that the solute molecular diameter (Table 2) must be at least one-tenth the size of the pore diameter of the packing material to avoid restricted diffusion of the solute and to allow the total surface of the sorbent material to be accessible. Therefore, compared with packings for separating small molecules, larger pore sizes of 15–100 nm or nonporous packing materials are needed for biopolymers.

3.1 Stationary Phase Support Materials and Functional Groups

Modern support materials used in HPLC are either derived from inorganic or organic polymers or are composites of these types. Inorganic supports comprise hydrous oxides (silica, alumina), phosphates (hydroxyapatite), silicates, porous glasses, and carbon materials. Usually, inorganic supports are hydrophilic (except for carbon, e.g. porous graphitic carbon) and possess acidic and/or basic functional groups. Cross-linked organic polymers exhibit a wide range of polarity, depending on the polymer backbone and the functional groups. The most prominent organic polymers include polyamide, polybutadiene, polysaccharides, polymethacrylates, poly(vinyl alcohol), and styrene–divinylbenzene copolymers. Silica-based packing materials are used in about 75% and

polymers in about 20% of all separations performed today.\textsuperscript{(10)}

Silica gel is available with irregular- and spherical-shaped particles and with a wide variety of particle diameters, pore diameters, and pore volumes. Moreover, silica-based stationary phases are mechanically stable, provide excellent efficiency, and can be converted to bonded-phase materials by virtue of their reactive silanol groups (see Silica Gel and its Derivatization for Liquid Chromatography). However, silica has some limitations: it dissolves rapidly at pH > 9 and the acidic silanol groups cause tailing or irreversible adsorption of basic compounds.

The most popular polymeric support is polystyrene cross-linked with divinylbenzene [poly(styrene/divinylbenzene) (PS/DVB)]. Depending on the degree of cross-linking and the amount of porogen used in their production, polymeric packings are also available with a variety of particle diameters, porosities, and mechanical strengths. Polymeric packings are generally stable over a wider pH range than silica gel, and some can operate throughout the full pH 0–14 range. Polymers do not exhibit silanol activity, however hydrophobic or charged entities of the polymer backbone can be a source of additional interactions resulting in multimode adsorption.

Both types of support materials, inorganic oxides or organic polymers, can be surface functionalized by well-established methods\textsuperscript{(11,12)} to obtain suitable stationary phases for the various chromatographic modes. Table 3 summarizes some of the most commonly used functionalities for the different modes of biopolymer chromatography.

A tremendous number of packing materials for different modes of chromatography are commercially available, and the market constantly changes with the introduction of new materials. Therefore, for the selection of a column for specific applications the reader is referred to comprehensive tables in recent monographs\textsuperscript{(13,14)} or periodical reviews appearing in analytical journals.\textsuperscript{(10,15,16)}

3.2 Stationary Phase Morphologies with Enhanced Mass Transfer Properties

Since slow mass transfer kinetics is often the limiting factor for speed and efficiency in biopolymer separations, the enhancement of intraparticle mass transport is particularly important for the rapid separation of large molecules having low diffusivities.\textsuperscript{(17,18)} The different routes to enhance the mass transfer of biopolymers in stationary phases include (1) increasing the pore diameter and decreasing the particle diameter, (2) eliminating the support pores by using nonporous stationary phases, (3) decreasing the pore depth by using superficially porous stationary phases, (4) introducing pores of 600–800 nm diameter transversing the particle that cause the liquid to flow through the particle, and
(5) using porous, continuous-bed polymers as the chromatographic bed.

The first attempts to adapt stationary phases for biopolymer separations applied small particles with large pores (macroporous particles)\(^9\) that yield enhanced column efficiency by virtue of the relatively small intraparticular mass transfer resistance due to the short diffusion distances (Figure 6a). Another way to circumvent intraparticle diffusion is the complete elimination of the support pores.\(^{19,20}\) Through the use of nonporous particles that lack any intraparticular pores, the only remaining particle-based diffusion limitations are in a thin layer of stagnant liquid at the surface of the particle (Figure 6b). The only limitation of nonporous sorbents is that they have approximately 1% of the surface area of porous sorbents and are, therefore, of limited loading capacity for preparative separations. This problem has been addressed by attaching a 1-µm thick layer of porous particles to the exterior surface of nonporous particles.\(^{21}\) These poreshell particles with a total diameter of around 5-µm have pores of 1 µm depth or less and a loading capacity around 65% of that of a totally porous particle.

Another approach to the problem of stagnant mobile phase mass transfer is to cause the liquid to flow (or perfuse) through the particles. Introduction of 600–800-nm pores transversing the particle allows a small portion of the mobile phase to perfuse the 600–800-nm pores transversing the particle allows a...
4.1 Ultraviolet/Visible Absorbance and Fluorescence Detection

Spectrophotometric techniques are among the most widely applicable for the detection of biopolymers. The absorbance maximum for the peptide bond is around 185 nm, but most eluents used for chromatographic separations absorb light strongly below 200 nm. Therefore, peptides and proteins are usually detected at wavelengths between 210 and 220 nm. Nevertheless, a host of other ultraviolet (UV)-absorbing compounds present in biological samples may cause interferences with separation and quantitation. In this situation, alternative wavelengths that can be monitored include the regions of absorbance of the side chains of tryptophan and tyrosine (280 nm) or, less commonly, phenylalanine (254 nm), cystine (240 nm), or histidine (228 nm). Proteins containing prosthetic groups, such as metalloproteins, often may be selectively detected in the far-UV or visible (VIS) region, the wavelength being dependent on the oxidation state of the metal. Cytochrome c oxidase may be detected near 410 nm, whereas myoglobin absorbs at 405 nm, cytochromes at 550–560 nm, and hemoglobin at 415 nm.\(^{(26)}\)

Nucleotides, the monomer units of nucleic acids, are UV active over the range 180–300 nm, with maxima at 180–200 and 250–280 nm. For the same reasons as described above for peptides and proteins, nucleic acids are normally detected at wavelengths between 250 and 260 nm. Polysaccharides are not ideal UV/VIS absorbers because of the absence of effective chromophores absorbing above 200 nm. Thus, underivatized polysaccharides have poor UV absorbance detection limits and other detection methods such as UV/VIS or FL detection after chemical derivatization or ELCSD have to be used.

FL detection generally has very low limits of detection (10–1000 times lower than UV/VIS detection) but, as only a few percent of all compounds exhibit native FL, the method is highly selective. Non-fluorescing compounds can be tagged with fluorescent dyes by pre- or postcolumn derivatization. The native FL of tryptophan and tyrosine can be used for peptide and protein detection. By exciting at 220 nm and monitoring at 330 nm, tryptophan-containing peptides are detected with six times lower detection limits compared with UV absorbance detection. Native nucleic acids and polysaccharides usually do not contain any fluorophore so that FL detection of these compounds is possible only after derivatization with an appropriate fluorescent label (see section 4.4).

4.2 Electrochemical Detection

In all forms of ELCD the analytes are detected by the current generated at a working electrode by oxidation or reduction. The direct electrochemistry of biopolymers on noble metal electrodes frequently suffers from electrode fouling due to adsorption of oxidized species at the electrode surface. This problem has been addressed by the application of pulsed ELCD, where the electrode undergoes oxidative cleaning followed by reductive regeneration of the electrode surface through the application of a triple-pulse waveform. If the current is measured only at a specific voltage during the pulse, the technique is known as pulsed amperometric detection (PAD).

Amino acids that respond to ELCD include tyrosine, tryptophan, methionine, and cysteine/cystine with the electroactive groups phenol, indole, thiocyste, thiol, and disulfide, respectively. ELCD is, therefore, mainly used for selective determination of peptides containing such amino acids. A more general strategy for the ELCD of peptides is taking advantage of complexation reactions between copper(II) and amino acids at a copper electrode.\(^{(27)}\) However, using ELCD for a wide range of peptides cannot currently be considered a general approach, since many peptides will not be detected.

Diffusion and proper orientation of the analyte to be oxidized or reduced at the electrode surface is of great importance in ELCD. The general use of ELCD for proteins is restricted by these two requirements, since proteins possess low diffusion coefficients and the electroactive groups may be buried inside the folded protein structure. Hence ELCD is restricted to certain specific proteins having special functionalities, e.g. heme groups,\(^{(28)}\) accessible disulfide bridges,\(^{(29)}\) or copper.\(^{(30)}\)

Electrochemical oxidation of the purine bases at a carbon electrode can be used to determine nucleic acids.\(^{(31)}\) The guanine and adenine bases can be readily distinguished owing to their different oxidation potentials (800 mV for guanine, 1080 mV for adenine versus Ag/AgCl). Nevertheless, like proteins, high molecular mass nucleic acids possess low diffusion coefficients, which eventually lead to poor sensitivity for larger nucleic acids.

PAD is the method of choice for detection of oligo- and polysaccharides with high sensitivity.\(^{(32)}\) Aldehyde and terminal alcohol moieties in oligosaccharides can be oxidized at gold electrodes in alkaline media. A typical triple-pulse waveform for detection of oligosaccharides involves anodic oxidation of the analytes at a potential of 50–200 mV for 200–400 ms, oxidative cleaning of the electrode surface at 600–800 mV for 120–180 ms, and reduction of the electrode surface at ~300 to 800 mV for 300–360 ms (Figure 7, all potentials versus Ag/AgCl).

4.3 Radioactivity Detection

Because of its very low detection limits, radioactivity (RA) detection of biopolymers is primarily applied in
studies involving very small amounts of sample in complex matrices. As the natural RA of the elements contained in biopolymers is extremely low, chemical or enzymatic labeling with radioelements of high specific activity is obligatory. Radioisotopes emitting β-radiation such as $^3$H, $^{14}$C, $^{32}$P, or $^{35}$S are the most commonly used radioactive labels. Examples of radioactive labeling reactions are given in Table 4.

4.4 Pre- and Postcolumn Derivatization

A chemical derivatization reaction allows the conversion of biopolymers with poor UV/VIS absorptivity or electrochemical activity into derivatives that can be detected with higher sensitivity. Moreover, chemical derivatization often enhances the selectivity when only certain functional groups characteristic of a biopolymer react during the derivatization procedure. Derivatizations can be performed before (precolumn) and after (postcolumn) a chromatographic separation. Postcolumn techniques allow the detection of biopolymers after separation in their native state, whereas precolumn derivatization changes both detection and chromatographic behavior. Tagging of biopolymers with FL labels is the method of

choice for derivatization because of the high sensitivity of FL detection (approximately 1000 times more sensitive than UV/VIS detection). Whereas FL derivatization of peptides, proteins and nucleic acids is necessary only when UV absorbance detection of the native compounds is not sensitive enough, derivatization of polysaccharides is very common owing to the lack of chromophoric or fluorogenic groups. Table 4 lists some examples of derivatization reagents used for UV/VIS, FL, ELCD, and RA detection of peptides, proteins, nucleic acids, and polysaccharides.

4.5 Mass Spectrometry

The molecular mass of a biopolymer is a very important parameter for its characterization and identification. Because most biopolymers are very polar and nonvolatile molecules, the classical MS methods such as electron ionization (EI) MS or chemical ionization (CI) MS are not applicable. However, the development of new, soft ionization techniques, such as fast atom bombardment (FAB),(48) electrospray ionization (ESI),(49) and matrix-assisted laser desorption/ionization (MALDI),(50) has made MS applicable as an LC detection system for biopolymers (see Atmospheric Pressure Ionization Mass Spectrometry).

While FAB ionization is confined to small biopolymers up to molecular mass \( M_r \) 15 000,\(^{(51)}\) ESI enables the transfer of proteins larger than \( M_r \) 130 000\(^{(52)}\) and of nucleic acids larger than \( M_r \) 7 000 000\(^{(53)}\) into the gas phase for mass analysis (Table 5). Moreover, electrospray ionization mass spectrometry (ESIMS) greatly benefits from the multiple charging of biopolymers resulting in mass-to-charge ratios well within the mass range of most commercial mass spectrometers (\( \leq 4000–6000 \) u) even for very large biomolecules. By virtue of its versatility for ionization of various biopolymers, broad mass range, high mass precision (typically 0.01\%), and tolerance for high eluent flow rates, the ESI interface is the most commonly used to couple LC and MS. MALDI/MS is frequently applied to the off-line analysis of collected fractions after chromatographic separation, although prototypes of continuous-flow MALDI interfaces have been reported.\(^{(54)}\)

4.6 Light-scattering Detection

A general property of macromolecular species is that they scatter light. The light intensity scattered by a biopolymer in solution at a certain angle of incidence depends on the molecular mass and concentration of the solute in the detector cell. LALLS detectors are capable of providing unique information about the molecular mass, radius of gyration, and diffusion coefficient of biopolymers in solution. To evaluate the molecular mass term, the LALLS detector is coupled in series to a concentration-dependent detector, such as the refractive index detector, and the response from both detectors is used to calculate the molecular mass without the need for external calibration standards.\(^{(55)}\) LALLS detection is very useful for the characterization of biopolymer aggregates formed in solution,\(^{(56)}\) information that cannot be accessed by MS.

5 INSTRUMENTAL REQUIREMENTS FOR CHROMATOGRAPHIC BIOPOLYMER SEPARATIONS

In principle, any liquid chromatograph can be used for biopolymer separations. All that is needed is a mobile phase delivery system, a sample injector, a separation column, a column thermostat, a detector (most commonly a UV absorbance detector), and a data system. Because the retentive properties of the individual components in a mixture of biopolymers can be very different, gradient elution capability is needed in most of the separation problems. The leaking of metal ions from the stainless-steel construction of the various parts of a conventional chromatograph may be a source of problems because many biopolymers interact with metal ions, resulting in irreversible adsorption or loss of biological activity of the analytes. Moreover, stainless steel rapidly corrodes with eluents containing halide salts such as those applied in IEC. To prevent this occurrence, all wetted parts of the so-called “biocompatible” liquid chromatographs are fabricated from inert materials such as titanium, glass, poly(tetrafluoroethylene) (PTFE), or poly(ether ether ketone) (PEEK).

6 SEPARATION OF PEPTIDES AND PROTEINS

The distinction between a peptide and a protein is somewhat arbitrary, with peptides usually being defined as molecules containing 50 amino acids or less. Molecules with >50 amino acids usually have a stable three-dimensional structure in aqueous solution and are referred to as proteins. Secondary structures such as $\alpha$-helix or $\beta$-sheet are generally absent for small peptides up to approximately 15 residues. However, the potential for defined secondary, tertiary, and quaternary structure increases with increasing chain length. Moreover, folding to internalize hydrophobic residues to stabilize the protein structure in aqueous solution is likely to become a significant conformational feature. This potential to form a variety of structures results in a large diversity of naturally occurring proteins and poses great challenges to separation techniques in terms of selectivity and resolution.

6.1 Size-exclusion Chromatography

SEC is frequently used as a first step in a purification scheme to separate the molecules of interest from those which have radically different size characteristics. It can also be used to change the buffer environment or for the desalting of a biopolymer sample. Finally, SEC can be implemented as a means of determining molecular parameters such as average molecular mass and hydrodynamic radius. Figure 8(a) illustrates a typical separation of proteins by SEC. The stationary phase used for this separation is SynChropak GPC 300, a controlled-porosity silica support having an average pore diameter of 30 nm with a glycerylpropylsilane bonded phase to prevent adsorptive protein retention. High molecular mass calf thymus DNA, which is completely excluded from the pores, is used as a marker for the void volume ($V_0$) whereas the small dipeptide glycyltyrosine can penetrate the total pore volume and serves as a noninteractive marker for the total volume ($V_t$). Solute with a molecular size between the two extremes are eluted at a volume ($V_e$) which is between $V_0$ and $V_t$. The distribution coefficient $K_d$ specifies the fraction of $V_t$ available to a molecule according to the relationship $V_e = V_0 + K_d V_t$. Under ideal size-exclusion conditions, the logarithm of the molecular mass is a linear function of the distribution coefficient and this relation can be used to define a calibration graph for protein molecular masses as a function of the elution volume (Figure 8b).

6.2 Ion-exchange Chromatography

Although RPC is the most commonly used chromatographic mode for the separation of peptides, IEC represents the most promising alternative if RPC fails to separate the components of interest. At a pH near neutrality, anion-exchange chromatography is used for acidic peptides and cation-exchange chromatography for basic peptides. However, cation-exchange chromatography becomes applicable to peptides in general if a pH in the range 2.8–3.0 is employed, where peptide retention will be governed by the basic residues of lysine, arginine, and histidine, and the N-terminus. Figure 9 demonstrates that peptides are eluted with a gradient of increasing salt concentration in order of increasing absolute number of positively charged residues. The ability of anion-exchange chromatography to resolve peptides of the same net charge is attributable to some sort of
LIQUID CHROMATOGRAPHY

Figure 9 Separation of peptide standards by cation-exchange chromatography. (Reprinted from A.J. Alpert, P.C. Andrews, ‘Cation-exchange Chromatography of Peptides on Poly(2-sulfoethylaspartamide) Silica’, J. Chromatogr., 443, 85–96 (1988), Copyright 1988, with permission from Elsevier Science.)

IEC is the method of choice for high-resolution separation of proteins in their native form without disrupting the three-dimensional structure. Figure 10 depicts the resolution of four standard proteins by anion-exchange chromatography on a stationary phase of the bimodal pore-size configuration (compare Figure 6c). A gradient of 0–0.35 M sodium chloride is applied to elute the proteins rapidly. The splitting of three of the four protein peaks into several incompletely resolved peaks and shoulders indicates the ability of IEC to distinguish between different isoforms of proteins, i.e. proteins of the same biological function but slightly different structure. The heterogeneity of ovalbumin (peak 3 in Figure 10), for instance, an Mr 43 000 glycoprophoroprotein consisting of 385 amino acids, is caused by oligosaccharides linked to asparagine 293 and two phosphorylation sites at serine 68 and serine 344.

The property of a protein which governs its retention in IEC is the net surface charge, which is highly pH related because of the presence of both weakly acidic and basic functional groups in proteins. The dependence of net charge of proteins on pH is a highly individual property of a protein and constitutes the basis for selectivity in IEC. At the isoelectric point, the net charge of a protein is zero and there should be no retention in IEC. However, experimental retention maps as a function of pH show that many proteins are retained on ion-exchange columns even when their net charge is zero (Figure 11), suggesting that the retention of proteins on ion-exchange stationary phases cannot be satisfactorily explained by the net charge concept alone. Deviations from this concept are mainly due to intramolecular charge asymmetry. Thus, regions of localized charges capable of interacting with oppositely charged functional groups on the surface of the stationary phase are present even at the isoelectric point.

In addition to the charge characteristics of the protein itself, the nature of the support surface and the displacing ion in the mobile phase are also important in determining the selectivity of an IEC separation system. The use of different displacing salts may result in retention variations of up to 100% and represents an easy and fast means of altering the selectivity of a chromatographic separation, as exemplified by the exchange of chloride by citrate as the displacing ion in the separation of soybean trypsin inhibitor and ovalbumin on a strong anion-exchange
column, which entails an increase in the separation factor from 1.50 to 2.61.\(^\text{(60)}\)

### 6.3 Reversed-phase and Hydrophobic Interaction Chromatography

The separation of peptide mixtures, particularly from proteolytic digests, is an important part of protein characterization. Peptide mapping by HPLC is routinely performed in the study of microheterogeneity, mutational variants, and isomers present in proteins. In the RPC of peptides and proteins, acids such as trifluoroacetic acid, phosphoric acid, hydrochloric acid, formic acid, and acetic acid are frequently used as mobile phase additives for the following reasons: (1) when silica-based stationary phases are employed, protonation of residual silanol groups on the support surface at low pH diminishes unwanted ionic interactions with the basic amino acid residues; (2) small organic acids form ion pairs with these basic sites and consequently increase the hydrophobic character of a peptide or protein; and (3) acidic solvents assist in the process of unfolding and denaturing the three-dimensional structure of a polypeptide, resulting in more homogeneous species that elute as sharper and more symmetric peaks. Trifluoroacetic acid is the most commonly used acid because it is volatile (unlike phosphoric acid), it does not corrode stainless-steel parts of the HPLC apparatus (unlike hydrochloric acid), and it is UV-transparent (unlike acetic and formic acid). The chromatogram of a tryptic digest of recombinant tissue plasminogen activator, a protein of 527 amino acids, on an octadecylated silica stationary phase using trifluoroacetic acid as mobile phase additive is shown in Figure 12.

The high selectivity and efficiency of the RPC of proteins is largely a consequence of the denaturing conditions applied (hydrophobic stationary phase, high concentration of organic solvent, low pH, elevated temperature). The potential efficiency of a 53 x 4 mm i.d. column packed with nonporous octadecylated PS/DVB is illustrated in Figure 13 by the high-resolution separation of 15 standard proteins in 13 min. The high selectivity of the separation system is reflected in the separation of the two \(\beta\)-lactoglobulins A and B, which differ by the substitution of only two amino acids in a total sequence of 162. \(\beta\)-Lactoglobulin B has a glycine at position 64 and an alanine at position 118, whereas \(\beta\)-lactoglobulin A contains aspartic acid and valine at the two respective positions.

The preparative purification of proteins by RPC suffers from poor recovery in terms of both total mass and biological activity. These observations are due to their strong interactions with the hydrophobic stationary phase and the strongly denaturing mobile phase conditions. HIC is an alternative chromatographic mode based on hydrophobic interactions, whereby the proteins are eluted from a weakly hydrophobic stationary phase by a decreasing salt gradient. Because the binding of the proteins to the stationary phase is weak compared with

RPC, and because organic solvents are generally not used, they may be eluted without conformational changes and retain their biological activity. The main variables controlling retention in HIC are hydrophobicity of the stationary phase, stationary phase ligand density and chain length, salt identity and concentration, gradient time and flow rate, pH, and temperature. Figure 14 illustrates the HIC of proteins on a hydrophilic derivatized silica stationary phase. The proteins are adsorbed at the stationary phase with 2 M ammonium sulfate and elute as the salt concentration is gradually decreased. (Reproduced from Z. El Rassi, C. Horvath, ‘Hydrophobic Interaction Chromatography of t-RNAs and Proteins’, J. Liq. Chromatogr., 9, 3245–3268 (1986), by permission of Marcel Dekker Inc.)

6.4 Metal Interaction and Affinity Chromatography

Transition metals are known to form complexes with electron-rich compounds such as the amino acids cysteine, histidine, tryptophan, lysine, and tyrosine. The different number of such amino acids and the differences in their steric accessibility in proteins can be used for their chromatographic separation. The transition metal is usually immobilized on the surface of a chromatographic support by means of a chelating functionality such as iminodiacetic acid (Figure 15a). Without metal, the iminodiacetic acid bonded stationary phase is expected to function as a cation exchanger. A typical chromatogram of a protein mixture separated under ion-exchange conditions at pH 5.0 is shown in Figure 15(b). However, the retention behavior of proteins is significantly altered upon chelation of Ni(II) (Figure 15c). It can be seen that the retention of most proteins increased and the selectivity changed considerably with the immobilized metal under otherwise identical conditions. In MIC, analytes are eluted with a gradient of increasing salt concentration, where the anion can be regarded as a competitive ligand for the coordination sites of the immobilized metal. The retention of proteins in MIC depends primarily on the number of ligands at the protein surface, the type and amount of immobilized metal, the strength of the protein–metal interaction, pH, and the type and concentration of displacing ion.

AC is the chromatographic method of highest specificity for proteins. The separation system is usually designed such that only one target molecule is recognized in very complex mixtures by taking advantage of highly specific biochemical interactions. Therefore, chromatographic efficiency is normally not a big issue in AC.
Figure 15 (a) Schematic illustration of the functional group in MIC and separation of proteins by (b) cation-exchange chromatography on iminodiacetate silica, and (c) MIC on Ni(II) iminodiacetate silica. Columns, unloaded (b) and Ni(II) loaded (c) iminodiacetate silica, 5 µm particle size, 30 nm pore size, 100 × 4.6 mm i.d.; mobile phase, (A) 25 mM phosphate, pH 5.0, (B) 0.5 M sodium chloride in (A); linear gradient, 16–100% B in 40 min; flow rate, 1 mL min⁻¹; temperature, 25 °C.

Figure 16(a) and (b) is a schematic illustration of AC. (a) The target molecule is adsorbed biospecifically on the column, whereas all other molecules pass the column without retention. (b) The target molecule is released from the column upon dissociation of the affinity ligand–target molecule complex.

of a competitive ligand which strongly binds either to the target molecule or the affinity ligand.

7 SEPARATION OF NUCLEIC ACIDS

Nucleic acid structures can be divided into four different types, namely single-stranded oligonucleotides (10–100 nucleotides in length), double-stranded linear DNA (10 to more than 10 000 base pairs in length), supercoiled DNA (several thousand base pairs), and single-stranded RNA. Oligonucleotides are relatively small molecules where both the hydrophilic sugar–phosphate backbone and the hydrophobic nucleobases are exposed to the solvent. In double-stranded DNA, a double-helical structure secludes the hydrophobic nucleobases inside the double helix, whereas the two helical sugar–phosphate chains spiral down the outside of the double-stranded structure, presenting a polyanionic and hydrophilic surface to the solvent. Supercoiled DNA is a special form of double-stranded DNA where closed circles of double-stranded DNA are wound around each other. Most single-stranded RNAs may be considered as having a globular structure with complementary sequences forming hairpin structures.

7.1 Size-exclusion Chromatography

Although SEC generally affords longer analysis times and lower resolution of oligonucleotides and DNA fragments
than IEC, mixed-mode chromatography, or IPRPC, it offers some advantages such as simple instrumentation, isocratic elution, great freedom of buffer choice, and elution in strict order of size. Resolution of mixtures of DNA fragments is achieved by selecting a stationary phase of a suitable pore-size distribution for the discrimination of molecular masses. The linear portion of a calibration graph generated by a polymer-based stationary phase containing >100-nm pores indicates (Figure 17) that this stationary phase is suitable for separating DNA fragments ranging in size from 100 to 7000 base pairs (one base pair has a mass of approximately 660).

7.2 Anion-exchange Chromatography

To fractionate polyanions such as nucleic acids, anion-exchange chromatography is the most obvious method. The negatively charged nucleic acids interact with the positively charged functional groups of the anion-exchange stationary phase and are desorbed by a gradient of increasing salt concentration. Figure 18 shows a separation of a hydrolysate of polydeoxyadenylic acid containing oligomers from the 17-mer through approximately the 100-mer on a nonporous, polymer based anion exchanger. Baseline separation is obtained for up to about the 32-mer and peaks appear for up to the 70-mer, the whole chromatogram taking only 20 min. Although the separation of homooligomers is strictly according to chain length, the base sequence of heterooligonucleotides has a significant impact in retention, most probably due to secondary interactions with the stationary phase and conformational influences. On a TSKgel DEAE NPR (diethylaminoethyl-derivatized hydrophilic polymer from TosoHaas) stationary phase, the retention of 12–18-mer oligonucleotides containing different bases increased in the order adenosine < thymidine < cytidine, whereas on a nonporous, quaternized PS/DVB anion exchanger the elution order was cytidine < adenosine < thymidine.64

The same stationary phase as used for the high-resolution separation of oligonucleotides can also be applied to the separation of double-stranded DNA fragments, as illustrated in Figure 19 by the fast separation of 22 DNA fragments of a 1-kilobase-pair ladder with fragments ranging in size from 75 to 12,216 base pairs. This separation demonstrates that IEC can separate DNA fragments with high resolution over an extremely broad size range in a fraction of the time that is needed for a size-exclusion separation (10 versus 130 min, compare Figure 17). The separation principle of anion-exchange chromatography implies that elution order is determined only by size because with double-stranded DNA, the hydrophobicity of the nucleobases is expected to have a minor influence on retention because they are secluded inside the double

![Figure 17](image-url) Relationship between elution volume and molecular mass in SEC of DNA fragments. Four TSKgel DNA-PW columns from Tosoh connected in series, 10 µm particle size, >100 nm pore size, 300 x 7.8 mm i.d.; mobile phase, 0.1 M TRIS–HCl–0.3 M sodium chloride, pH 7.5; flow rate, 0.3 mL min⁻¹; sample, EcoRI-cleaved pBR322 DNA and BstNI-cleaved pBR322 DNA. Chromatogr.* 320, 440–444 (1985), Copyright 1985, with permission from Elsevier Science.)

![Figure 18](image-url) Anion-exchange separation of oligodeoxyadenylic acids. Two TSKgel DEAE NPR (diethylaminoethyl-derivatized hydrophilic polymer from TosoHaas) columns connected in series, 25 µm particle size, nonporous, 35 x 4.6 mm i.d.; mobile phase, (A) 20 mM TRIS–HCl, pH 9.0, (B) 1 M sodium chloride in (A); linear gradient, 25–100% B in 60 min; flow rate, 1 mL min⁻¹; temperature, 25°C. Peaks are identified by the number of adenosine units in the oligomer. (Reprinted from Y. Kato, T. Kitamura, A. Mitsui, Y. Yamasaki, T. Hashimoto, T. Murotsu, S. Fukushige, K. Matsubara, ‘Separation of Oligonucleotides by High-performance Ion-exchange Chromatography on a Nonporous Ion Exchanger’, *J. Chromatogr.* 447, 212–220 (1988), Copyright 1988, with permission from Elsevier Science.)
helix. However, anion-exchange separation of double-stranded DNA fragments on a variety of different stationary phases has suffered from inversions in retention time as a function of chain length, preventing its use for size-accurate fragment identification (compare, e.g. the elution order of the 220 and 201 base-pair fragments or the 1636 and 1018 base-pair fragments in Figure 19). A more length-relevant separation of DNA fragments at the cost of lower resolution is feasible when a gradient of tetraethylammonium chloride is applied instead of sodium chloride.

7.3 Ion-Pair Reversed-phase Chromatography

Retention of nucleic acids is effected predominantly by electrostatic interactions both in anion-exchange chromatography and in IPRPC. However, the two chromatographic modes differ in the way in which the surface potential is generated at the stationary phase. Whereas anion exchangers have the charged functional groups covalently bound to the surface, the amphiphilic ions generating the surface potential in IPRPC are adsorbed through hydrophobic interactions on the surface of a reversed-phase stationary phase. The surface concentration of the amphiphile strongly depends on the concentration of organic modifier in the eluent, which offers a simple means of controlling the retention of the analytes in IPRPC. The most popular amphiphiles for the IPRPC of nucleic acids are trialkylammonium and tetraalkylammonium ions, where the alkyl chains vary from methyl to butyl. Common gradient formers are acetonitrile, methanol, and 2-propanol.

Figure 20 depicts the separation of a homologous series of oligodeoxyadenylic acids by IPRPC on a nonporous, octadecylated PS/DVB stationary phase. With a total separation time of 28 min, baseline separation is obtained up to about the 50-mer and peaks appear up to the 90-mer. Compared with anion-exchange chromatography, the influence of base composition on the retention behavior of oligonucleotides is more pronounced in IPRPC owing to additional hydrophobic interactions of the nucleobases with the hydrophobic stationary phase, the elution order of 4-mer homooligonucleotides being tetradeoxyguanosine < tetradeoxycytidine < tetradeoxyadenosine < tetradeoxythymidine.

IPRPC is also suitable for the separation of double-stranded DNA fragments. Figure 21 shows the chromatogram of a mixture of four different restriction digests of the plasmids pBR322 and pBR328 containing 45 DNA fragments. Of these, 39 fragments are of different size and are separated into 33 at least partially resolved peaks. Compared with anion-exchange chromatography, IPRPC can separate DNA fragments up to a chain length of 2000...
base pairs with higher resolution, whereas the former can better separate long DNA fragments (>2000 base pairs). In IPRPC, the retention of double-stranded nucleic acids is size dependent to a very high degree, which allows the calculation of fragment size from retention data with an accuracy of better than 3.2%. Moreover, the correlation between size and retention time is almost linear up to 500 base pairs and then slowly levels off up to 2000 base pairs.

One important additional feature of IPRPC is the sequence-dependent retention of double-stranded DNA fragments at temperatures higher than 55 °C due to partial denaturation. The temperature at which the separation of the two DNA strands begins is determined by the total number and extent of repetitive AT tracts in a DNA fragment and thus depends on the DNA sequence. The perturbation of the helical structure in partially denatured DNA fragments as a consequence of opening of the double strand results in decreased retention compared with completely double helical fragments of the same length because of a smaller contact area with the stationary phase.

### 7.4 Mixed-mode Chromatography

With mixed-mode chromatography, the separation of the analytes relies upon at least two different modes of interaction between the solute and the stationary phase. Although with many types of stationary phases the separation can be regarded as the result of mixed-mode processes, generally the additional modes of interaction are a minor effect and can be minimized through the appropriate choice of mobile phase parameters. In order to provide solute retention by mixed interactions, it is necessary that the stationary phase be multifunctional in character. In the case of nucleic acids, mixed electrostatic and hydrophobic interaction are most successfully employed. The two methods for the preparation of mixed-mode stationary phases for electrostatic and hydrophobic interaction are the introduction of hydrophobic moieties on to an ion-exchange packing (e.g. through alklylation of the amino groups of aminopropylsilica) or the introduction of sites for electrostatic interaction into a reversed-phase stationary phase (e.g. through adsorption of methyltriolithiumammonium chloride on octadecylsilica).

Mixed-mode supports have proven to be very valuable for separating tRNAs by mixed-mode chromatography. Elution of tRNAs is performed with a combined gradient of increasing ammonium acetate concentration and increasing pH.

---

**Figure 21** High-resolution IPRPC separation of DNA fragments. Column, octadecylated PS/DVB from Transgenomic, 2.3 µm particle size, nonporous, 50 x 4.6 mm i.d.; mobile phase, (A) 0.1 M triethylammonium acetate, pH 7.0, (B) 25% acetonitrile in (A); linear gradient, 38–54% B in 10 min, 33–36% B in 7 min, 54–62% B in 8 min, 62–71% B in 15 min; flow rate, 0.75 mL min⁻¹; temperature, 50 °C; sample, *Hae*III-cleaved *pBR322* DNA, *Alu*I-cleaved *pBR322* DNA, *Bgl*I-cleaved *pBR328* DNA, and *Hinf*I-cleaved *pBR328* DNA. Peaks are identified by the number of base pairs in the DNA fragment. In IPRPC, the retention of double-stranded nucleic acids is size dependent to a very high degree, which allows the calculation of fragment size from retention data with an accuracy of better than 3.2%. Moreover, the correlation between size and retention time is almost linear up to 500 base pairs and then slowly levels off up to 2000 base pairs. One important additional feature of IPRPC is the sequence-dependent retention of double-stranded DNA fragments at temperatures higher than 55 °C due to partial denaturation. The temperature at which the separation of the two DNA strands begins is determined by the total number and extent of repetitive AT tracts in a DNA fragment and thus depends on the DNA sequence. The perturbation of the helical structure in partially denatured DNA fragments as a consequence of opening of the double strand results in decreased retention compared with completely double helical fragments of the same length because of a smaller contact area with the stationary phase.

**Figure 22** AC of polyadenosine mRNA from *Saccharomyces*. Column, silica gel, derivatized with (dT)₃₈, 7 µm particle size, 30 nm pore size, 30 x 4.6 mm i.d.; mobile phase, (A) 10 mM phosphate, pH 7.0–1 M sodium chloride, (B) 5 mM phosphate, pH 7.0; temperature and salt gradient as indicated; flow rate, 1 mL min⁻¹. Peak identification: see text. (Reprinted from T.A. Goss, M. Bard, H.W. Jarrett, ‘High-performance Affinity Chromatography of Messenger RNA’, *J. Chromatogr.* 588, 157–164 (1991), Copyright 1991, with permission from Elsevier Science.)
7.5 Affinity Chromatography

The AC of nucleic acids involves the highly selective base pairing of two complementary polynucleotide strands. By attaching single-stranded oligonucleotides to a chromatographic support, nucleic acids containing a sequence complementary to the immobilized sequence are retained by the column. Figure 22 shows as an example the selective isolation of mRNA from *Saccharomyces* containing polyadenosine tracts at their 3'-ends. Using a silica stationary phase with an immobilized oligodeoxythymidine 18-mer [(dT)₁₈] and a combination of salt and temperature gradients, mRNA can be purified in as little as 8 min. The first, unretained peak contains rRNA and nonpolyadenylated mRNA and the second peak contains mRNA with short stretches of polyadenosine with less than 15 adenosine units. The third peak represents the bulk of the polyadenosine mRNA with tail lengths of 15–80 units. The fourth peak contains mRNA with long polyadenosine tails of about 80 units.

8 SEPARATION OF OLIGO- AND POLYSACCHARIDES

Oligo- and polysaccharides can have an enormous number of possible structures because of the various configurations possible for monosaccharides, their variable linkage forms, the possibility of α- and β-anomers at the glycoside linkage, and their different branching patterns. While the linkage of three different amino acids can result in only six different tripeptides, three different carbohydrates can theoretically form more than 700 trisaccharides. Furthermore, saccharides are diversified by the presence of nonglycosyl substituents. Oligosaccharides have covalent structures of 2–25 usually different monosaccharide residues joined by glycosidic linkages, resulting in linear, branched, or cyclic chains. Polysaccharides are polymeric forms of repeating mono-, di-, or tetrasaccharides. Naturally occurring polysaccharides may range in molecular mass from a few thousand to several million.

8.1 Size-exclusion Chromatography

SEC is the method of choice for the separation of high molecular mass polysaccharides. With appropriate stationary phases of smaller pore size, it is also applicable to the separation of oligosaccharides, although possibly with lower resolution than that offered by IEC. With saccharides, having a high portion of hydroxyl and other polar groups, interaction with a polar stationary phase is likely to induce unwanted adsorption unless the ionic strength of the mobile phase is high enough (0.1–1 M) to exclude such interaction. SEC has found application in the carbohydrate field mainly as a means of fractionation and molecular mass determination of polysaccharides. Calibration is a general problem in SEC of polysaccharides because standard substances of known molecular mass are not readily available for all structural types of polysaccharides. However, advances in detection methods such as LALLS detection largely overcome this drawback and, furthermore, enable the extraction of information on polymer branching and conformation from size-exclusion data.

8.2 Normal- and Reversed-phase Chromatography

By virtue of their two different retention mechanisms, NPC and RPC are complementary separation techniques and should be used in conjunction for the isolation and analysis of oligosaccharides. A normal-phase separation of maltotriosaccharides is depicted in Figure 23. The substances are eluted in the order of their increasing molecular mass. Baseline separation up to the 17-mer is obtained on an aminopropylsila stationary phase with a gradient of 25–75% water in acetonitrile. The oligosaccharides are in the form of their 4-nitrophenylglycosides which are detected by their absorbance at 300 nm. Alternatively, the same sample can be separated by RPC on an octadecylsila stationary phase (ODS-Hypersil from Shandon) with a gradient...
High-pH anion-exchange chromatography is uniquely able to resolve structural isomers of oligosaccharides derived from glycoproteins or complex biological samples. Detection of carbohydrates at high pH conditions poses a problem. Pre- and postcolumn derivatization methods have been largely replaced by PAD at gold electrodes, which works well under alkaline conditions. Moreover, PAD is characterized by low detection limits and relatively high specificity for compounds with hydroxyl groups. The high-pH anion-exchange separation of matooligosaccharides on a nonporous PS/DVB stationary phase with covalently bound trimethylammonium groups is shown in Figure 24. The oligomers are eluted with a gradient of 0–0.2 M sodium acetate in 50 mM sodium hydroxide and baseline resolution of the oligomers is feasible at least up to the 20-mer.

8.4 Metal Interaction Chromatography

Separations of mono- and oligosaccharides on 5–10% cross-linked PS/DVB sulfonic acid cation exchangers in the hydrogen form are mainly due to the size-exclusion effect in the swollen polymer gels. The degree of cross-linking of a resin is important because separation can only take place when the sample molecules penetrate at least partially into the matrix. For this reason, cation-exchange resins for the analysis of oligosaccharides usually have from 4 to 90% acetonitrile in water with similar, but slightly lower, resolution.

8.3 Ion-exchange Chromatography

Since carbohydrates are weak acids with pKₐ values ranging from 12 to 14 they dissociate under highly alkaline conditions and can be separated directly at high pH by anion-exchange chromatography. Elution at high pH allows the separation of saccharides as their oxoanions. This approach cannot be used with silica-based stationary phases owing to their poor stability at high pH. Therefore, a range of polymeric, nonporous ion exchangers has been developed by Dionex. These stationary phases consist of 5–10-µm nonporous core particles on to which a layer of quaternary ammonium anion-exchange microbeads (<0.1 µm) is attached by electrostatic interactions, providing rapid mass transport, high ion-exchange capacity, and high chemical and mechanical stability.
a lower degree of cross-linking than those optimized for the separation of monomers. Silver ions are known to form fairly stable monodentate complexes with most monosaccharides. This complex formation also brings about greater retention of oligosaccharides on silver-loaded cation-exchange resins and allows more species to be resolved from the excluded high molecular mass polysaccharides. In the complex formation of saccharides with metal ions, the hydroxyl groups are thought to form coordinate bonds with the metal ion. The stability of the complexes depends both on the type of metal ion and on the configuration of the hydroxyl groups in the saccharides. The separation of oligosaccharides obtained by the hydrolysis of corn syrup is illustrated in Figure 25. Oligomers up to the 10-mer are separated on a 5% cross-linked cation exchanger that is loaded with 71% silver ions.

9 MODERN TRENDS AND FUTURE DEVELOPMENTS

9.1 Miniaturization of Separation Systems

One of the clear trends in science and technology is miniaturization, which is also a permanent goal in analytical chemistry, where the growing interest in analyzing minute samples of high complexity is the driving force for the rapid development of miniaturized techniques. One of the most important innovations in the field of miniaturized separation has been the introduction of fused-silica capillaries, which gave birth to several miniaturized separation techniques including capillary gas chromatography (GC), capillary LC, capillary electrophoresis (CE), and capillary electrochromatography (CEC) (see Microscale High-performance Liquid Chromatography and the Evolution of Capillary Electrophromatography). Basically, four major advantages connected with the use of smaller dimensions in LC separation techniques can be specified: (1) better resolving power can be accomplished in a shorter time; (2) smaller samples can be analyzed; (3) on-line conjugation to MS is feasible; and (4) expenses connected with consumption and disposal of materials are decreased.

Miniaturization of column technology is usually the first step in the development of a miniaturized LC separation system. Today, four major types of microcolumns can be distinguished: (1) open-tubular microcolumns; (2) partially packed capillary columns; (3) tightly packed capillary columns; and (4) continuous-bed capillary columns. Column inner diameters down to 5–20 μm have been realized with these types of capillary columns. The downscaling factor, which corresponds to the square of the ratio of the column diameters, for the reduction of the column inner diameter, e.g. from the traditional 4.6 mm to 25 μm, is 33856, which means that all parameters related to the volume, including volumetric flow rate, injection volume, and detection volume, have to be divided by the downscaling factor. Thus, a capillary column of 25 μm i.d. is operated at a flow rate of around 30 nL min⁻¹ and a few tenths of a nanoliter are injected, allowing the chromatographic analysis of attomole to zeptomole amounts of biopolymers.

However, the low flow rates and detection volumes represent considerable challenges to reliable instrumentation for miniaturized LC, and miniaturized versions of conventional instruments frequently fail to provide the required performance. Therefore, alternative principles for pumping and detecting devices, such as pumps based on thermal expansion or electroosmosis and detection devices based on microelectrodes, laser light, or MS have been developed. One of the strongest supports in microtechnology is provided by microelectronics. Advances in manufacturing processes, namely silicon micromachining techniques, are the basis for miniaturization of liquid-phase separation techniques down to the submicrometer level. Figure 26 shows an electron micrograph of the inlet and part of the chromatographic bed of a microfabricated column which was machined by lithography on a silicon wafer. Hundreds of such column structures on a single wafer are possible based on the ease with which millions of submicrometer-sized structural features are micro-machined into silicon wafers. This represents a great potential for multiplexing of miniaturized liquid-phase separation technology.

Figure 26 Scanning electron micrograph showing the column inlet and part of the stationary phase of a nanocolumn structure microfabricated on a quartz wafer. (Reprinted with permission from B. He, N. Tait, F.E. Regnier, ‘Fabrication of Nanocolumns for Liquid Chromatography’, Anal. Chem., 70, 3790–3797 (1998), Copyright 1998 American Chemical Society.)
9.2 Multidimensional Separation of Biopolymers and Coupling to Mass Spectrometry

Although single-stage chromatographic separation systems offer high selectivity and resolving power for biopolymers, the total peak capacity may not suffice to separate all the components of interest contained in complex mixtures of biological origin. A practical means of increasing the selectivity of a separation system is the use of two or more separation stages, resulting in the multidimensional separation of a biopolymer mixture. The two criteria for multidimensional separation are that the sample components are displaced by two or more separation techniques based on different separation mechanisms and that the components separated by any single separation dimension must not be recombined in any further separation dimension. The two separation dimensions should ideally be orthogonal, i.e. separate the analyte according to different molecular properties. The key feature of a multidimensional system is that all analytes composing the initially injected sample are eventually transferred to all further separation stages.

In column LC, utilization of the total available separation selectivity would require a large number of secondary columns, so that all the sample cuts taken while eluting from the first dimension could be transferred to the second dimension. In practice, however, definite fractions of the separations taken in the first dimension are studied in the second dimension, a technique that is conventionally termed coupled-column LC. If the timescale for the first dimension is of the order of a few minutes for one eluting peak, whereas that for the second dimension is of the order of a few seconds per peak, analytes eluting from the first stage of separation can be sampled and analyzed in real time in the second stage without loss of the separation in the first dimension. The requirement for such a fast separation in the second dimension is ideally met by RPC. Therefore, the most frequently used combinations of separation dimensions for the multidimensional LC separation of protein mixtures are SEC/RPC and IEC/RPC.

MS is generally viewed as a spectroscopic technique yielding both the molecular mass and structural information from fragmentation and is used as a powerful detection method for the analytes separated by LC (see Liquid Chromatography/Mass Spectrometry). However, it can also be viewed as a separation technique distinguishing between different mass-to-charge ratios. Therefore, according to the definition given above, conjugation of LC and MS represents a multidimensional separation system. Two MS ionization techniques for biopolymers are considered to be most compatible with the flow rates identified with microscale liquid-phase separations: CFFAB and ESI. It is more difficult to couple MALDI directly to liquid-phase separations, because samples have to be mixed with a matrix and dried on a solid surface before insertion into the mass spectrometer. Therefore, MALDI MS is mainly used as off-line detection of fractions collected from LC.

Coupled reversed-phase HPLC with ESIMS has emerged as a very powerful tool for the identification of known protein sequences and also for the de novo sequencing of proteins. The most effective method is the combination of chemical or proteolytic digestion of a protein followed by reversed-phase separation and identification of the resulting peptide sequences by tandem MS. In tandem MS, ions of a single mass-to-charge ratio are selected for transmission through the first mass analyzer and into a cell for collision-induced dissociation, where the peptides fragment to create patterns characteristic of a specific amino acid sequence. These are subsequently detected by means of a second mass analyzer. With the help of a computer algorithm, the experimental patterns can be compared and matched with calculated patterns obtained from databases containing the sequences of all known proteins. This method allows the rapid and fully automated identification of the proteins in whole cell lysates from uninterpreted tandem mass spectra of tryptic peptides by comparison with sequences in a protein database. Unknown protein sequences can be deduced from the sequence-specific pattern in the mass spectrum of the fragmented peptide.

A schematic diagram of an on-line multidimensional separation system for proteins is illustrated in Figure 27.

The three applied separation dimensions involve cation-exchange chromatography, RPC, and MS. Sample components eluting from the cation-exchange column are sampled by an eight-port valve and subsequently injected onto a reversed-phase column. The eluate from RPC is split into a UV detector and an ESI mass spectrometer. One 120-min cation-exchange run is sampled by 48 individual 150-s duration reversed-phase runs and mass spectra from $m/z$ 1000 to 2000 are recorded every 2 s. The peaks eluting from the cation-exchange column are approximately 6 min wide. With a time between the injection peak and the last-eluting peak of 100 min, a maximum peak capacity of 16 in the first dimension can be achieved. A peak width of about 5 s and an available elution time of 60 s give a peak capacity of 32 in the second dimension. Taking the inherent peak capacity of MS as 5, because it can identify at least this number of components in the $m/z$ 1000–2000 mass range, the peak capacity of the entire three-dimensional system amounts to $>2500$, which is sufficient even for complicated biological mixtures.

9.3 Capillary Electrochromatography

CEC is an electrokinetic separation technique that is expected to combine the versatility offered by HPLC with the high plate efficiency of CE (see Microscale High-performance Liquid Chromatography and the Evolution of Capillary Electrochromatography). The technique employs fused-silica capillaries packed with a stationary phase that has fixed charges at the surface. Thus, upon application of a high electric field, flow of eluent across the column is generated and maintained by electro-osmotic means. The diffuse part of the electrical double layer, which exists at all interfaces between a solid and an electrolyte solution, responds to the driving force of the electric field generating the flat flow profile characteristic for electroosmotically driven flow.

CEC promises much higher plate efficiencies than microcolumn HPLC with packed capillary columns. Furthermore, CEC offers a higher sample loading capacity and a wider range of selectivity than CE. The unique electro-osmotic flow field allows the use of long capillary columns packed with small particles, resulting in significant gains in peak capacity. CEC is applicable to the analysis of neutral and charged compounds. The sample components are separated on the basis of differences in their chromatographic partitioning between the mobile and the stationary phase and, if charged, also differences in their electrophoretic mobilities. The potential of CEC for the analysis of biopolymers lies in increased peak capacity owing to higher selectivity because of the two different separation mechanisms involved (chromatography and electrophoresis) and higher efficiency because of the flat electro-osmotic flow profile. Figure 28 shows the separation of standard proteins by gradient reversed-phase CEC in a monolithic capillary column.

**ABBREVIATIONS AND ACRONYMS**

- AC: Affinity Chromatography
- CE: Capillary Electrophoresis
- CEC: Capillary Electrochromatography
- CFFAB: Continuous-flow Fast Atom Bombardment
- CI: Chemical Ionization
- EI: Electron Ionization
- ELCD: Electrochemical Detection
- ESI: Electrospray Ionization
- ESI MS: Electrospray Ionization Mass Spectrometry
- FAB: Fast Atom Bombardment
- FL: Fluorescence
- GC: Gas Chromatography
- HIC: Hydrophobic Interaction Chromatography
HPLC  High-performance Liquid Chromatography
IEC  Ion-exchange Chromatography
IPRPC Ion-pair Reversed-phase Chromatography
LALLS  Low-angle Laser Light Scattering
LC  Liquid Chromatography
MALDI  Matrix-assisted Laser Desorption/ Ionization
MIC  Metal Interaction Chromatography
MS  Mass Spectrometry
NPC  Normal-phase Chromatography
PAD  Pulsed Amperometric Detection
PEEK  Poly(ether ether ketone)
PS/DVB  Poly(styrene/divinylbenzene)
PTFE  Poly(tetrafluoroethylene)
RA  Radioactivity
RPC  Reversed-phase Chromatography
SEC  Size-exclusion Chromatography
TRIS  Tris(hydroxymethyl)aminomethane
UV  Ultraviolet
VIS  Visible

University of Denver Research Institute, Denver, USA

1 Historical Background

Fundamental developments in the understanding of electrolysis, the electrical double layer, displacement electrophoresis, moving boundary electrophoresis, and other phenomena over the course of a 200-year period led to the emergence of CE as a family of powerful separation techniques. In 1967, Hjerten was the first to report free solution electrophoresis, conducted in 3-mm inner diameter (ID) capillary tubes. The full advantages of this technique could not be realized until methods to introduce smaller quantities into the capillary tubes were developed to avoid sample overloading. In addition, the use of narrower bore capillary tubing (25–100 µm ID), with greater heat dissipation, would allow the use of higher field strengths (up to 900 V cm⁻¹) for faster and more efficient separations. In 1981, these advantages were realized by Jorgenson and Lukacs in what is considered the first report of modern FSCIE utilising a BGE and potentially a variety of BGE additives, several alternative separation modes have been developed and implemented. These include micellar electrokinetic chromatography (MEKC), capillary isoelectric focusing (cIEF), size-sieving capillary electrophoresis (SSCE), and capillary electrochromatography (CEC). Some of these separation modes have been adapted from the slab gel electrophoresis (SGE) format, or are reminiscent of separation mechanisms in liquid chromatography (LC). Currently, one of the greatest challenges in CE involves the maintenance of the capillary surface to provide reproducible electro-osmotic flow (EOF) and significantly reduce capillary wall interactions. According to the mode of separation employed and the characteristics of the solutes to be analysed, both covalent and noncovalent (dynamic) capillary wall modifications have been demonstrated.

1 HISTORICAL BACKGROUND

Over the past two decades, capillary electrophoresis (CE) has emerged as a family of powerful and versatile separation techniques. The electrically driven flow profiles generated in CE provide, routinely, separation efficiencies of 10⁶ theoretical plates. Although theory predicts that the achievable separation efficiencies will be greatest for macromolecules with small diffusion coefficients, CE has also been successful in the analysis of small molecules, such as inorganic ions. Strategies to increase separation efficiencies on-line have involved sample stacking and isotachophoretic techniques. The former promotes higher separation efficiencies based on differences in conductivity between the background electrolyte (BGE) and the sample buffer; the latter utilizes a discontinuous buffer system to create discrete solute zones. The instrumentation employed in CE is simple in design and is compatible with a variety of detection modes, including ultraviolet/visible (UV/VIS) absorbance, fluorescence, electrochemistry, mass spectrometry (MS), and chemiluminescence (CL). CE methodologies can be miniaturized on to a silicon wafer and integrated with sample preparation and chemical reactions. In addition to free-solution capillary electrophoresis (FSCIE) utilising a BGE and potentially a variety of BGE additives, several alternative separation modes have been developed and implemented. These include micellar electrokinetic chromatography (MEKC), capillary isoelectric focusing (cIEF), size-sieving capillary electrophoresis (SSCE), and capillary electrochromatography (CEC). Some of these separation modes have been adapted from the slab gel electrophoresis (SGE) format, or are reminiscent of separation mechanisms in liquid chromatography (LC). Currently, one of the greatest challenges in CE involves the maintenance of the capillary surface to provide reproducible electro-osmotic flow (EOF) and significantly reduce capillary wall interactions. According to the mode of separation employed and the characteristics of the solutes to be analyzed, both covalent and noncovalent (dynamic) capillary wall modifications have been demonstrated.

1 HISTORICAL BACKGROUND

Fundamental developments in the understanding of electrolysis, the electrical double layer, displacement electrophoresis, moving boundary electrophoresis, and other phenomena over the course of a 200-year period led to the emergence of CE as a family of powerful separation techniques. In 1967, Hjerten was the first to report free solution electrophoresis, conducted in 3-mm inner diameter (ID) capillary tubes. The full advantages of this technique could not be realized until methods to introduce smaller quantities into the capillary tubes were developed to avoid sample overloading. In addition, the use of narrower bore capillary tubing (25–100 µm ID), with greater heat dissipation, would allow the use of higher field strengths (up to 900 V cm⁻¹) for faster and more efficient separations. In 1981, these advantages were realized by Jorgenson and Lukacs in what is considered the first report of modern FSCIE or capillary zone electrophoresis (CZE). Since then, other landmark developments have been made including the development of MEKC. The development of
microchip CE,\(^{(4)}\) and the development of CEC.\(^{(5)}\) We are now closing in on the second decade of modern CE separations, performed in narrow-bore fused-silica tubing. Currently, CE pervades many areas of analysis encompassing organic, inorganic, environmental, pharmaceutical, and biotechnological applications. Initially it was predicted that CE would replace modern LC in terms of solving difficult separation problems. However CE, being fundamentally different in its principle of separation, appears to complement separations performed using LC. Currently, commercial CE equipment is in its third generation, utilizing microtiter plates for high sample throughput and appropriate interfaces for MS detection.

### 2 PRINCIPLES OF CAPILLARY ELECTROPHORESIS

#### 2.1 Theory

The electrophoretic mobility, \(\mu_{ep}\), of an ionic species migrating through a medium in an electrical field is directly proportional to electrical forces and inversely proportional to frictional forces acting on the ion (Equation 1):

\[
\mu_{ep} \propto \frac{\text{electrical force} (F_e)}{\text{frictional force} (F_f)}
\]

In an electrical field, ions are accelerated by the electrical force \(F_e\), which is a function of field strength, \(E\), and charge of the ion, \(q\) (Equation 2):

\[
F_e = qE
\]

The opposing frictional force acting on a spherical species is defined by Equation (3):

\[
F_f = -6\pi\eta rv
\]

where \(\eta\) is the viscosity of the electrophoretic medium, \(r\) is the radius of the solvated species, and \(v\) is its velocity. The ionic species reaches a steady state when electrical forces are balanced with frictional forces. Hence, equating Equations (2) and (3), electrophoretic mobility can be defined according to Equation (4):

\[
\mu_{ep} = \frac{q}{6\pi\eta r}
\]

Electrophoretic mobility is also the proportionality constant between the electrophoretic velocity and the applied field strength, \(E\) (Equation 5):

\[
v_{ep} = \mu_{ep}E = \frac{\mu_{ep}V}{L_t}
\]

where \(V\) is the applied voltage and \(L_t\) is the total capillary length. The apparent mobility, \(\mu_{app}\), of a species is the vector sum of its electrophoretic mobility, \(\mu_{ep}\), and the electro-osmotic mobility, \(\mu_{eof}\), due to the presence of EOF inside the capillary (Equation 6):

\[
\mu_{app} = \mu_{ep} + \mu_{eof}
\]

EOF refers to the migration of fluids along the length of the capillary. In a buffer-filled, fused-silica capillary, an electrical double layer is established at the interface of the electrolyte solution and the fused-silica capillary surface (Figure 1). The weakly acidic silanol groups at the capillary surface exist in either the protonated or the deprotonated form according to the following chemical equilibrium (Equation 7):

\[
\text{SiOH} \rightleftharpoons \text{SiO}^- + \text{H}_\text{aq}^+
\]

At buffer pH values greater than approximately 2, the capillary wall is negatively charged. Cations surrounded by their waters of hydration are strongly attracted to and partially neutralize the negatively charged silanol sites, forming the compact layer. A diffuse layer, consisting of

![Figure 1](image-url)
hydted cations, anions, and neutral species, is formed adjacent to the compact layer, neutralizing the remaining negative charge. Under the influence of a longitudinally applied electrical field, the diffuse layer and the bulk solution migrate toward the negatively charged cathode, generating EOF. The zeta potential, \( \zeta \), is the potential formed across the two layers of cations at the capillary wall and is defined according to Equation (8):

\[
\zeta = \frac{4\pi \delta e}{\varepsilon}
\]

The zeta potential is a function of the thickness of the double layer, \( \delta \), the charge per unit of surface area, \( e \), and the dielectric constant of the electrophoretic medium, \( \varepsilon \). The thickness of the double layer is a function of buffer composition and is independent of the applied potential. The EOF velocity of a buffer system is given by Equation (9):

\[
v_{\text{eof}} = \frac{\zeta}{\eta} E
\]

demonstrating that the magnitude of EOF may be modified by altering characteristics of the BGE, such as its pH, ionic strength, and viscosity. Note that EOF velocity is independent of the capillary dimensions.

Cations will migrate toward the negatively charged electrode (the cathode); anions will migrate toward the positively charged electrode (the anode) unless EOF is sufficient in magnitude to reverse the direction of their migration. Neutral species demonstrate no inherent electrophoretic mobility and hence migrate at the EOF velocity. Therefore, EOF can be determined for a particular system by introducing a neutral solute and observing its migration time, \( t \), as given in Equation (10):

\[
t = \frac{L_i L_d}{\mu_{\text{app}} V}
\]

where \( L_i \) is the total capillary length, \( L_d \) is the effective capillary length from the injection end of the capillary to the detector, \( \mu_{\text{app}} \) is the apparent mobility, and \( V \) is the applied voltage. EOF may be effectively eliminated by covalently or dynamically coating the capillary surface, and in that event \( \mu_{\text{app}} = \mu_{\text{ep}} \).

2.2 Separation Parameters and Peak Shape

At the point of injection, a sample zone will be infinitesimally narrow. As migration through the capillary proceeds, a concentration gradient will be encountered as a function of time, \( t \), and the distance migrated from the initial point, \( x \), to generate a peak Gaussian in shape that can be described by Equation (11):\(^{(6)}\)

\[
C_{x,t} = \frac{k}{2(Dt)^{0.5}} \exp\left(-\frac{(x - v_{\text{ep}}t)^2}{4Dt}\right)
\]

where \( C_{x,t} \) is the solute concentration, \( k \) is a constant, \( D \) is the diffusion coefficient of the solute, and \( v_{\text{ep}} \) is the electrophoretic velocity of the solute. Integration of Equation (11) yields a mathematical expression that describes the resulting concentration–distance profile. The electrophoretic peak width is influenced directly by the shape of the solute profile within the capillary. Peak width is often measured as variance, \( \sigma \), which is the standard deviation for a Gaussian distribution. Variance is related to the diffusion coefficient of the analyte, \( D \), and the time, \( t \), that the solute is allowed to diffuse from an infinitesimally narrow zone (Equation 12):

\[
\sigma^2 = 2Dt
\]

Combining Equations (10) and (12) yields a description of peak variance in relation to the apparent electrophoretic mobility of the solute (Equation 13):

\[
\sigma^2 = \frac{2DL_{\text{ed}}}{\mu_{\text{app}} E}
\]

The theoretical plate height, \( H \), is the proportionality constant between the variance of an electrophoretic peak and the distance that the corresponding solute zone has traveled through a capillary (Equation 14):

\[
H = \frac{2Dt}{L_d} = \frac{2DL_{\text{ed}}}{\mu_{\text{app}} V}
\]

The concept of theoretical plate height was developed originally to describe separation efficiency in chromatographic techniques. Later, this concept was adapted by Giddings to electrophoretic techniques.\(^{(7)}\)

The van Deemter equation (Equation 15) summarizes the dependence of plate height on on-column band broadening phenomena in chromatographic (partitioning) processes:

\[
H = A + \frac{B}{\mu_x} + C\mu_x
\]

where \( A, B, \) and \( C \) are constants for a specified separation system, and \( \mu_x \) is the eluent linear flow rate. The first term, \( A \), describes band broadening due to multiple paths in a packed column. The second term, \( B/\mu_x \), represents band broadening due to longitudinal diffusion. The third term, \( C\mu_x \), describes the contribution of resistance to mass transfer to band broadening due to the equilibration of an analyte between the stationary phase and the mobile phase. The multiple path term \( (A) \) and the resistance to mass transfer term \( (C\mu_x) \) do not contribute to band broadening in CE, as no stationary phase is present. Therefore, under ideal CE separation conditions, the only on-column contribution to band broadening is longitudinal diffusion. The electrically driven, nearly plug flow profiles produced in CE result in inherently higher...
Each factor of Equation (17) will now be defined. For a
The total variance for an electrophoretic peak,
$s$s, can be described as a sum of all plate height contributions
(Equation 16):

$$H_T = \frac{\sigma^2_{\text{tot}}}{L_t}$$

(16)

The total variance for an electrophoretic peak, $\sigma^2_{\text{tot}}$, can be considered as the sum of dispersive phenomena on a
solute zone in addition to the variance due to diffusion,
$\sigma^2_{\text{dif}}$ (Equation 17):

$$\sigma^2_{\text{tot}} = \sigma^2_{\text{dif}} + \sigma^2_{\text{inj}} + \sigma^2_{\text{wall}}$$

(17)

Each factor of Equation (17) will now be defined. For a
more detailed theoretical discussion, the reader is referred elsewhere.\(^{(8)}\)

Parabolic temperature gradients across the capillary,
caused by undissipated Joule heating, contribute to band broadening;\(^{(9)}\) the variance associated with this phenomenon is approximated by Equation (18)\(^{(10)}\) for capillaries with radii between 25 and 50 $\mu$m:

$$\sigma^2_T = \frac{r^6E^2C_b^2B^2K^2t}{1536DK_0^2T^4}$$

(18)

where $r$ is the capillary radius, $E$ is the applied field strength, $C_b$ is the concentration of the BGE, $B$ is a constant associated with the viscosity of the BGE, $K$ is the conductance of the BGE, $t$ is time, $D$ is the diffusion coefficient of the solute, $K_0$ is the thermal conductivity of the BGE, and $T$ is absolute temperature. Equation (18) demonstrates the importance of employing narrow-bore separation capillaries in CE.

Injection of a sample zone greater than approximately
1 mm in length\(^{(11)}\) promotes another form of peak variance, $\sigma^2_{\text{inj}}$, as given by Equation (19):\(^{(12)}\)

$$\sigma^2_{\text{inj}} = \frac{l_{\text{inj}}^2}{12}$$

(19)

where $l_{\text{inj}}$ is the length of the injected (approximately rectangular) sample plug.

Non-Gaussian peak shapes may be caused also by solute adsorption to the internal capillary wall,\(^{(13)}\) as given by Equation (20)\(^{(14)}\) at a specified temperature:

$$\sigma^2_{\text{wall}} = L_t \left\{ \frac{f^2}{12L_t} + \frac{2D}{\mu_s} + \frac{k'\mu}{(1+k')^2} \left( \frac{r^2}{4D} + \frac{2}{k_d} \right) \right\}$$

(20)

where $l$ is the length of the solute zone, $L_t$ is the total capillary length, $D$ is the diffusion coefficient of the solute, $\mu_s$ is the linear BGE flow rate, $k'$ is the retention factor, $r$ is the capillary radius, and $k_d$ is the first-order rate constant for dissociation of the solute from the capillary surface. The solute–capillary wall interactions are usually solute-specific.

Mismatched conductivity between the sample zone and the BGE can alter the electrophoretic mobilities of the corresponding ions, generating non-Gaussian peak shapes. In general, if the mobility of the BGE co-ion is higher than the mobility of the solute ion, peak “tailing” will be observed, whereas, the converse results in peak “fronting”. Experimentally, actual peak shapes may deviate from these generalized predictions. Using a mathematical model, Gebauer and Bocek were able to predict peak symmetry as a function of BGE concentration and pH according to peak shape diagrams.\(^{(15)}\)

In addition, laminar flow with parabolic-shaped flow profiles may be caused by siphoning between buffer reservoirs with uneven liquid levels; laminar flow is also present in the front end of a hydrodynamically introduced sample zone. Separation efficiency can be compromised further by the finite detection window volume, or coiling of the separation capillary, with greater band broadening observed for smaller capillary radii.\(^{(16)}\)

The dimensionless parameter of efficiency, $N$, is related to the following previously defined parameters (Equation 21):

$$N = \frac{L_t}{H} = \frac{\mu_{\text{app}}V}{2D}$$

(21)

Hence the efficiency of a band in CE is a function of applied voltage and is not dependent on capillary length at a constant voltage. Higher applied voltages will yield faster analyses times and higher separation efficiencies, assuming that the Joule heating generated is dissipated sufficiently. In addition, theory predicts that separation efficiency will be high for a large solute with a small diffusion coefficient. Theoretical efficiencies (typically greater than 10$^5$) are greater generally than those determined experimentally due to the aforementioned extracolumn band broadening phenomena.
Resolution, $R_s$, is a dimensionless parameter that accounts for both analyte migration and peak dispersion in describing the degree of separation between two analytes (Equation 22):

$$R_s = \left(\frac{1}{4}\right) \frac{\Delta \mu_{app}}{\mu_{app}} N^{1/2}$$

It follows that resolution may be increased by increasing the applied voltage. However, resolution increases by the factor $V^{1/2}$, hence the Joule heat produced at higher applied voltages will dictate a practical limit. Resolution may also be increased by decreasing EOF or reversing the flow of an analyte (counter to EOF). Since the analysis time, and hence band broadening, will increase as a result, an optimization trade-off is realized. The pH of the BGE can influence resolution according to the charge and mobility of individual analytes in addition to the relative mobilities of analytes. Relative analyte mobility is described by selectivity, $\alpha$, for solutes $i$ and $j$ (Equation 23):

$$\alpha = \frac{\mu_{app,i}}{\mu_{app,j}}$$

where, by definition, $\alpha$ is always greater than 1. Alternatively, resolution may also be calculated directly from an electropherogram according to Equation (24):

$$R_s = \frac{2(t_i - t_j)}{w_{b,i} + w_{b,j}}$$

where $t$ is the migration time of the analytes and $w_b$ is peak width at the baseline of a Gaussian peak ($w = 4\sigma$) in time units.

3 INSTRUMENTATION

3.1 Introduction

A CE system is simple in design (Figure 3). The necessary components include two electrolyte reservoirs [a source (inlet) vial and a destination (outlet) vial], a separation capillary, a high-voltage power supply, a detector, and a data acquisition device for data collection and readout. In order to perform a sample “injection”, the inlet buffer reservoir is replaced by the sample vial, and nanoliters of sample solution are introduced into the capillary either electrokinetically or hydrodynamically. In order to perform a CE separation, the sample vial is replaced by the inlet electrolyte reservoir and the power supply is turned on. It is imperative that the electrolyte levels of the inlet and outlet vials are equalized in height in order to eliminate siphoning effects. The capillary can be liquid-cooled or air-cooled in order to dissipate Joule heating and improve the reproducibility of analyses. A variety of detectors have been employed in CE as described in section 3.5.

3.2 The High-voltage Power Supply

The electrical field and resulting EOF in CE are established using a direct current high-voltage power supply. In the normal polarity mode, the high-voltage cable is connected to the anode that resides in the electrolyte inlet reservoir; the ground cable is connected to the cathode that resides in the electrolyte outlet reservoir. The reversed polarity mode, where the anode and cathode of the system are switched, may be necessary for various separation mechanisms. The range of operation is typically from $-30$ to $+30\,\text{kV}$, with a resulting operating current range of $\pm300\,\text{µA}$. Access to the high-voltage electrode should be safety interlocked. Usually, a constant voltage is applied, although constant current and constant power modes can be applied as well. Field strength gradients can be applied to enhance separation performance.\(^{17}\) Two 30-kV high-voltage power supplies can be used simultaneously, one connected to the anode and the other to the cathode, to apply up to $60\,\text{kV}$. High-voltage power supplies have also been adapted to run in the pulsed-field mode for the analysis of large molecules.\(^{18}\)

3.3 The Separation Capillary

Fused silica is the most commonly used substrate for separation capillaries, providing both mechanical and chemical stability. The capillaries are coated externally with polyimide for enhanced strength and durability. A small (1-cm) section of the external polyimide coating is removed for alignment in an optical detector. Capillary IDs of 10–100 µm allow efficient dissipation of Joule heating produced during the application of high voltages. The

Figure 3 Schematic diagram of a CE instrument (not drawn to scale). (Reproduced by permission of Academic Press, Inc., from A. Weston, P.R. Brown, ‘Instrumentation for Capillary Electrophoresis’, HPLC and CE: Principles and Practice, Academic Press, San Diego, Chapter 6, 186, 1997.)
use of narrower bore capillaries can provide higher efficiencies, but limits the concentration sensitivity of optical detectors. Narrower bore capillaries are also susceptible to obstruction by microparticulates. Capillary lengths are typically 30–100 cm. Alternative capillary substrates and geometries have been explored briefly.\(^{(19,20)}\) Shorter capillaries facilitate faster analysis times, but are more susceptible to sample overload. The ends of the capillary should be cleaved using a ceramic cutting tool by scoring the capillary in a single direction and pulling straight apart. This assures flat capillary edges that are advantageous especially during hydrodynamic sample introduction.

### 3.4 Sample Introduction

In CE, nanoliter sample volumes must be introduced efficiently and reproducibly. The two most common modes of sample introduction are hydrodynamic and electrokinetic. For hydrodynamic sample introduction, positive pressure is applied to the sample vial, negative pressure (vacuum) is applied to the outlet electrolyte vial, or the sample vial is elevated relative to the outlet reservoir in order to create a siphoning effect. Hydrodynamic sample introduction is nondiscriminatory, that is, the analyte and matrix components are introduced into the capillary in a manner that represents the original sample composition. If positive or negative pressure is applied, Equation (25) can be used to calculate the sample volume injected, \(V_{\text{inj}}\):

\[
V_{\text{inj}} = \frac{\Delta P d^4 \pi t_{\text{inj}}}{128 \eta L_t}
\]

where \(\Delta P\) is the pressure differential, \(d\) is the capillary ID, \(t_{\text{inj}}\) is the time of injection, \(\eta\) is the buffer viscosity, and \(L_t\) is the total capillary length. The main disadvantages of hydrodynamic sample introduction are that run-to-run reproducibilities are dependent on atmospheric pressure, the condition of the instrumentation, and the viscosity of the sample solution. Additionally, hydrodynamic sample introduction introduces a laminar flow profile to the front end of the sample zone which contributes to band broadening.

Alternatively, samples can be introduced into the capillary electrokinetically. In this mode of sample introduction, the inlet buffer reservoir is replaced by the sample vial and a high voltage is applied across the capillary for a short period of time. Both EOF and electroosmotic mobilities contribute to the electrophoretic velocity of the sample species; the latter become concentrated in the narrow zone. Sample stacking is a simple and universal way to increase simultaneously the peak efficiency and detection sensitivity. This is based upon conductivity differences between the solute zone and the BGE; typically, a 1 : 10 ratio of sample zone and BGE conductivities produces a Gaussian peak shape. When the separation potential is applied, the sample zone experiences a greater electrical field than the BGE owing to its lower conductance. Ions in the sample zone migrate rapidly until reaching the concentration boundary of the BGE. Positive species stack towards the front of the sample zone, negative species stack towards the back of the sample zone, and neutral species remain in the central portion of the sample zone. The higher conductivity of the BGE decreases the electroosmotic mobility of the sample species; the latter become concentrated in the narrow zone. Sample stacking and detection sensitivity. This is based upon conductivity differences between the solute zone and the BGE; typically, a 1 : 10 ratio of sample zone and BGE conductivities produces a Gaussian peak shape. When the separation potential is applied, the sample zone experiences a greater electrical field than the BGE owing to its lower conductance. Ions in the sample zone migrate rapidly until reaching the concentration boundary of the BGE. Positive species stack towards the front of the sample zone, negative species stack towards the back of the sample zone, and neutral species remain in the central portion of the sample zone. The higher conductivity of the BGE decreases the electroosmotic velocity of the sample species; the latter become concentrated in the narrow zone. Sample stacking has been applied in a variety of applications such as the analysis of neutral solutes in MEKC,\(^{(21)}\) ultratrace environmental samples,\(^{(22)}\) and DNA fragments.\(^{(23)}\)

Trace analytes in dilute samples, especially those with complex matrices, may be concentrated up to 10 000-fold by the on-line coupling of isotachophoresis (ITP) with FSCE.\(^{(24)}\) In ITP, analyte bands migrate at a constant velocity in an applied electrical field, positioned between a leading electrolyte and a terminating electrolyte of a discontinuous buffer system. The width of each discrete, “stacked” solute zone adjusts to maintain the same concentration as the leading electrolyte. Once the analyte bands reach the FSCE capillary, they migrate according to their velocity in a particular BGE and are separated. ITP preconcentration has been applied to the CE analysis of pharmaceutical samples,\(^{(25)}\) the fractionation of human serum proteins from biological samples,\(^{(26)}\) and chlorophenols in river and industrial wastewaters.\(^{(27)}\)

### 3.5 Modes of Detection

The majority of detectors that have been applied in CE were adapted from LC. However, CE requires more stringent specifications owing to its narrower, lower volume solute zones. The CE detection method chosen for a particular application should reflect the

\[
Q = (\mu_{\text{ep}} + \mu_{\text{eof}}) \frac{K_B}{K_S} E \pi r^2 C t
\]

where \(\mu_{\text{ep}}\) and \(\mu_{\text{eof}}\) are the electrophoretic and electroosmotic mobilities, respectively, \(K_B/K_S\) is the ratio of conductivity of the buffer to the solute, \(E\) is the applied field strength, \(r\) is the internal capillary radius, \(C\) is the analyte concentration, and \(t\) is the time of injection. This method of sample introduction introduces sample bias as smaller, more mobile species in the sample matrix may be injected preferentially over larger, less mobile species. This in turn may lead to sample depletion over time and does not allow for accurate quantitation of sample components with different electrophoretic mobilities. Sample stacking is a simple and universal way to increase simultaneously the peak efficiency and detection sensitivity. This is based upon conductivity differences between the solute zone and the BGE; typically, a 1 : 10 ratio of sample zone and BGE conductivities produces a Gaussian peak shape. When the separation potential is applied, the sample zone experiences a greater electrical field than the BGE owing to its lower conductance. Ions in the sample zone migrate rapidly until reaching the concentration boundary of the BGE. Positive species stack towards the front of the sample zone, negative species stack towards the back of the sample zone, and neutral species remain in the central portion of the sample zone. The higher conductivity of the BGE decreases the electroosmotic velocity of the sample species; the latter become concentrated in the narrow zone. Sample stacking has been applied in a variety of applications such as the analysis of neutral solutes in MEKC,\(^{(21)}\) ultratrace environmental samples,\(^{(22)}\) and DNA fragments.\(^{(23)}\)

Trace analytes in dilute samples, especially those with complex matrices, may be concentrated up to 10 000-fold by the on-line coupling of isotachophoresis (ITP) with FSCE.\(^{(24)}\) In ITP, analyte bands migrate at a constant velocity in an applied electrical field, positioned between a leading electrolyte and a terminating electrolyte of a discontinuous buffer system. The width of each discrete, “stacked” solute zone adjusts to maintain the same concentration as the leading electrolyte. Once the analyte bands reach the FSCE capillary, they migrate according to their velocity in a particular BGE and are separated. ITP preconcentration has been applied to the CE analysis of pharmaceutical samples,\(^{(25)}\) the fractionation of human serum proteins from biological samples,\(^{(26)}\) and chlorophenols in river and industrial wastewaters.\(^{(27)}\)
properties of the analyte and its sample matrix, in addition to the separation mode and BGE employed. The dynamic range, sensitivity, and selectivity of the detection method should be considered also. Detector response times of approximately 100 ms are adequate to preserve simultaneously the separation performance and detection sensitivity. For optical detection methods, on-column detection is used where a portion of the outer capillary coating is removed to create the detection window.

Many compounds possess chromophores that absorb light in the ultraviolet (UV) (190–350 nm) or visible (VIS) (350–700 nm) regions of the electromagnetic spectrum; alternatively, nonabsorbing compounds can be derivatized with UV/VIS-absorbing chromophores. As a result, the most common on-column detection mode is UV/VIS absorbance spectrophotometry. The widespread applicability of this detection mode is attributed also to its low maintenance and relatively low cost. Beer’s law is observed theoretically for on-column absorbance (A) measurements (Equation 27):

\[ A = \varepsilon b C \]  (27)

where \( \varepsilon \) is the molar absorptivity of the chromophore, \( b \) is the path length (in this case, the ID of the capillary), and \( C \) is the analyte concentration. Hence the narrow capillary dimensions limit the concentration sensitivity of this detection technique. Attempts have been made to enhance detection concentration sensitivity beyond the commonly observed range of 10^{-7} – 10^{-5} M by increasing the optical path length, in “Z-cells” or “bubble cells”.

In the former, a section of the capillary is bent and absorbance is measured longitudinally down the central portion of the “Z”; in the latter, the ID of the capillary at the detection window is increased three to five times. The most common light source in UV detectors is a deuterium arc lamp, although low-pressure atomic vapor lamps can also be used. A tungsten–halogen lamp is employed commonly in the VIS range. Laser light sources have also been employed in order to enhance detection sensitivity.

In a conventional, variable-wavelength UV/VIS absorbance detector, a monochromator (single-wavelength selector containing a diffraction grating) and photon transducer (detector) are employed in a “forward” optics design. Alternatively, a polychromator and a photodiode array (PDA) detector may be employed in a “reverse” optics design where the positions of the diffraction grating and the capillary window are reversed. The polychromator allows the simultaneous detection of analyte absorbance at multiple wavelengths; the PDA detector can be advantageous in the confirmation of peak purity and in the identification of components in a mixture. Culbertson and Jorgenson increased the signal-to-noise ratio of a 1500-diode PDA by a factor of 85 by collecting and averaging electropherograms from individual diodes. Fiber optics can be used instead of ball lenses, to collect and focus light from the capillary on to the detector. Additionally, a charge-coupled device (CCD) camera can be incorporated into the UV detection system where absorbance is recorded in two dimensions, as a function of both capillary distance and wavelength.

UV/VIS absorbance detection may be applied more universally in the indirect mode. A strongly UV/VIS-absorbing chromophore is added to the BGE to provide a stable background absorbance signal. Solute zones are detected as “negative” peaks owing to their displacement of the background absorbance. Typically, limits of detection are an order of magnitude poorer in the indirect mode of UV/VIS absorbance than the direct mode. To maintain a Gaussian peak shape, the electrophoretic mobilities of the analytes and the background chromophore should be comparable.

Fluorescence detectors are inherently more sensitive than UV/VIS absorbance detectors, making single-molecule detection in the VIS range a reality. In CE, femtomolar limits of detection have been achieved over a wide range of path lengths (capillary diameters), and linear dynamic ranges characteristically span several orders of magnitude. As molecular fluorescence is less common than UV/VIS absorbance, fluorescence detection is inherently more selective. In simple, on-column fluorescence detection, excitation radiation produced from a light source passes through a monochrometer and is focused on the capillary window. Fluorescent emission from the sample within the capillary then passes through a second monochromator that is at a 90\(^\circ\) angle to the excitation light path, and ultimately impinges upon a photomultiplier tube for signal detection. Intense light sources such as high-pressure mercury lamps and xenon pulse flash lamps have been applied. The use of Ar\(^+\), He–Cd, or diode lasers as fluorescent light sources provides enhanced focusing capabilities and reduces stray light for enhanced limits of detection. However, wavelength selection can be limited with laser light sources and such high light intensities can cause photodegradation. In order to reduce the spectral background associated with the capillary walls, postcolumn and sheath-flow cell designs have been constructed. For further enhancement of detection limits, the fluorescent emission can be collected using a microscope objective or an optical fiber. Wavelength-resolved fluorescence detection utilizing a PDA or a CCD camera has been applied to obtain qualitative analyte information without sacrificing sensitivity. Time-resolved fluorescence measurements have been applied to discriminate against background Rayleigh and Raman scattering. Numerous derivatization chemistries have been employed to impart fluorescence to nonfluorescent
For on-line detection, the electrochemical cell current (100 fA) is isolated from the electrophoretic current (100 µA) by creating a fracture or gap between the separation portion of the capillary and the detector portion of the capillary (Figure 4a). A grounded joint constructed from porous glass, porous graphite, or Nafion surrounds the fracture or gap and eliminates the need to place the outlet end of the capillary in a buffer reservoir. The joints can be prone to leakage and breakage, and introduce band broadening. In the end-column format, the detection electrode may be micropositioned at the end of the separation capillary (Figure 4b). To facilitate the placement of the electrode, and hence the precision of analysis, the capillary end can be etched chemically to a greater ID (Figure 4c). Detection limits comparable to those reported for on-line detection are approached as the outer diameter of the electrode approaches the ID of the capillary.

Amperometry is the most sensitive and most commonly employed mode of CE/ED. The current arising from the oxidation or reduction of an analyte is measured when a constant potential is applied between the reference electrode and the working electrode. Chemically modified electrodes can be utilized to facilitate slow electron transfer kinetics. Voltammetry, measuring current as the applied potential is scanned, can be employed to provide qualitative analyte information. Detection utilizing ion-selective electrodes has been applied less frequently in CE.

Conductivity detection is an alternative, nearly universal mode of detection in CE that has been applied to the analysis of both organic and inorganic ions. Detection limits are similar to those achieved using UV/VIS absorbance detection. A pair of inert electrodes is inserted into the sides of a capillary and aligned carefully in an on-, off-, or end-column arrangement. A small, constant current is applied between the two electrodes, and the conductivity of the BGE is measured. The presence of an ion in the BGE with a differing conductivity will be detected as a solute zone. As in amperometric ED, the challenge in designing a conductivity detector is the isolation of the electrophoretic potential from the electrochemical measurement. The on-column configuration may be more challenging to construct reproducibly, but resolution can be enhanced owing to the characteristically low detector dead volume. The end-capillary configuration has the potential disadvantage of extraband broadening, but the advantage of versatility in coupling with different capillaries. The suppressed conductivity detection mode achieves lower detection limits than the nonsuppressed mode. In the former, an ion-exchange
membrane is placed at the end of the separation capillary for suppression of the conductivity of the BGE.\(^{55}\)

Unique applications of CE/ED include single cell analyses\(^ {56}\) and the coupling of CE/ED with microdialysis for the analysis of electrochemically active species in living animals.\(^ {47}\) Future advances point to the further development of electrochemical array detectors for the analysis of dynamic electrochemical and separation processes.\(^ {57}\)

Capillary electrophoresis/mass spectrometry (CE/MS) achieves effectively two-dimensional separations, combining the high separation efficiency of CE with the ability to determine mass and structural elements of a molecule. However, interfacing CE with MS detection presents significant challenges experimentally and instrumentally. First, restrictions are placed on the BGE; those containing alkali metals, surfactants, or size-sieving polymers can be particularly problematic. Acidic buffers of low ionic strength tend to yield high detection sensitivity;\(^ {58}\) organic cosolvents can also be beneficial as well.\(^ {59}\) Second, even though mass detection limits are in the low-femtomole range, concentration detection limits are in the \(10^{-5} - 10^{-4}\) M range.\(^ {60}\) To circumvent this problem via CE, sample stacking, ITP, and on-line sample preconcentration can be employed. To circumvent this problem via MS, alternative interface designs, mass analyzers, and detectors can be investigated.

Three different sample ionization processes have been coupled with CE: electrospray ionization (ESI), continuous-flow fast atom bombardment (CFFAB), and matrix-assisted laser desorption/ionization (MALDI). In ESI, eluate flows from the end of the capillary through a needle held at a potential of approximately \(3\) kV at atmospheric pressure.\(^ {61}\) Solvent is evaporated quickly by the surrounding flow of a hot gas, and molecules (typically less than \(100,000\) Da) are ionized prior to entering the MS analyzer. In fast atom bombardment (FAB), the sample is mixed with a glycerol-based matrix (to avoid freezing of the solvent in the low-pressure conditions) and deposited directly on a probe tip. Subsequent impact with high-energy (8–10 keV) species such as xenon molecules causes desorption of the sample into the gas phase. The continuous-flow version (CFFAB) has been demonstrated for molecules smaller than \(3000\) Da.\(^ {62}\) MALDI has been almost exclusively limited to off-line analyses in CE.

Common interfaces used in CE/MS include sheath flow, sheathless flow, and liquid junction (Figure 5a–c). In the sheath-flow design, a conducting, sheathing solution is added in a 100:1 ratio relative to the BGE exiting the capillary.\(^ {63}\) This is of utility for both ESI and CFFAB that require higher liquid flow rates than that provided by EOF (microliters versus nanoliters per minute). The sheathless-flow interface at low flow rates has been used in conjunction with ESI for enhanced sensitivity owing to a reduced level of background ions.\(^ {64}\) In the liquid-junction design, the separation capillary does not enter the mass spectrometer. The outlet end of the capillary and a transfer line are positioned end-to-end, separated by a \(50\)-µm gap.\(^ {65}\) A reservoir of make-up fluid surrounds the gap to promote fluid transfer.

To enhance the sensitivity of analysis in CE/MS, selected-ion monitoring (SIM) is a viable technique. In SIM, the mass spectrometer detects only a small range of mass/charge ratios as opposed to a full spectrum of mass/charge ratios. In addition to quadrupole and magnetic sector mass analyzers, time-of-flight (TOF),\(^ {65}\) ion-trap\(^ {66}\) and Fourier transform (FT) ion cyclotron mass analyzers\(^ {67}\) have been used to improve sensitivity marginally. The FT mode of MS can offer additional enhancement in mass resolution capabilities.

**Figure 5** Different types of CE/MS interfaces: (a) sheath flow; (b) sheathless flow; and (c) liquid junction. (Reproduced by permission of John Wiley & Sons, Inc. from J.F. Banks, Electrophoresis, 18, 2255–2266 (1997).)
The applications of CE/MS have been plentiful. Particularly successful applications have involved the determination of impurities in peptide and protein samples and the determination of drug metabolites in urine. Currently, the majority of instrumentation for CE/MS is in the developmental stage. As commercial instrumentation and interfaces between CE units and mass spectrometers progress, the scope and promise of CE/MS are expected to grow.

Alternative, less common detection modes have been explored in conjunction with CE. CL detection is analogous to fluorescence detection, but the analyte molecules are excited by a chemical reaction as opposed to a high-intensity light source. Detection limits for CL are intermediate between those for UV/VIS absorbance and fluorescence detection. Refractive index (RI) detectors measure changes in the RI of the BGE as analytes migrate across the capillary window. Although RI detectors are universal in application, they demonstrate low selectivity and low concentration sensitivity, and are extremely prone to interferences. Radionuclide detection offers high selectivity and sensitivity in association with CE, but can introduce obvious health hazards in the laboratory. Radiation from the first-order radioactive decay of a particular nuclide (such as $^{14}\text{C}$, $^{11}\text{C}$, $^{99}\text{Tc}$, $^{32}\text{P}$, or $^{18}\text{F}$) is exposed to a scintillation device that converts the radiation into photons for detection. More recently, Raman spectroscopy, nuclear magnetic resonance (NMR) spectroscopy, and light scattering detection modes have been applied in CE.

### 3.6 Microchip Capillary Electrophoresis

Microfabricated separation devices are miniaturized analytical systems that integrate sample introduction, electrophoretic separation, and in some instances chemical reactions, on a planar chip or wafer (Figure 6a). These postage-stamp-sized devices can manipulate picoliter volumes of liquid electrokinetically without external valves or pumps through separation channels that are micrometers in length. Higher electrical field strengths (up to 2500 V cm$^{-1}$) relative to conventional CE may be applied due to enhanced Joule heat dissipation. As a result, higher separation efficiencies may be achieved and analyses may be performed nearly 100 times faster (less than 1 ms in some instances) (Figure 6b). Shorter analysis times minimize longitudinal diffusion and further reduce band broadening.

Insulating substrate materials, such as glass or fused quartz, can be microfabricated as CE microchips using standard photolithographic techniques and wet-chemical etching procedures. The glass or fused-quartz wafers are annealed thermally, polished mechanically, cleaned, and sputter-coated with a metal layer, typically gold and chromium. A positive photoresist layer, approximately 1–2 µm in thickness, is then spin-coated on the surface. A photomask is applied and the wafer is exposed to UV light, producing the desired channel pattern. The exposed metal layers are removed and channels are etched using an acid bath to reveal the channel pattern. Finally, the etched wafer and cover plate are cleaned, aligned, and thermally bonded to form capillary channels. Holes are drilled to allow access to the channels. The bonding process can be repeated to eliminate defects. Further
CAPILLARY ELECTROPHORESIS

Differences between substrates should be noted. The usage of glass results in more background noise. Additionally, glass fluoresces at 325 nm, whereas quartz does not fluoresce. Despite their less desirable optical properties, glass substrates are used predominantly owing to their ease of micromachining and bonding. An alternative microchip substrate is a flexible poly(dimethylsiloxane) (PDMS) silicone elastomer that is molded to a microfabricated silicon master with a raised, etched channel pattern. A solution consisting of Sylgard 184 and its curing agent is poured over the wafer and allowed to cure for several hours. The PDMS slab is peeled away; holes are punched to allow access to the channels. The PDMS slab is then encased in a solid, rectangular, PDMS container. PDMS offers several benefits over glass or quartz substrates. The fabrication of PDMS microchips is more time and cost efficient. In the event that channels or holes of the device become clogged, the molded PDMS slab may be removed from the solid PDMS encasement, rinsed, dried, and reused. PDMS has a low RI of 1.430, lessening the magnitude of excitation light reflected in optical detection schemes. Overall, PDMS substrates are less advantageous electrically, thermally, and optically relative to glass or fused quartz.

Prior to sample injection, the channels are flushed hydrodynamically with a buffer solution using a syringe or pipet. Platinum electrodes are placed into the inlet and outlet reservoirs for the application of voltage. Samples are injected electrokinetically; automation of sample injection enhances the reproducibility of migration times and reduces sample diffusion.

Channel geometry influences the sample introduction process, and hence the overall performance of the CE microchip. Three basic components, the straight channel, the “T”, and the cross, can be combined to produce simple to sophisticated channel patterns. The “double-T” injector provides high separation efficiency. In this configuration, the channel connecting the sample and sample waste reservoirs intersects perpendicularly with the separation channel (Figure 6a). Potential is applied between the sample and sample waste reservoirs. Once the slowest moving analyte has entered the intersection, the potential is switched and applied across the separation channel only. The sample plug in the intersection is swept down the separation channel and is detected. The latter is referred to as “floating injection” and yields sufficient relative standard deviation (RSD) values of approximately 2%. This injection technique can allow leakage and eddy mixing of the sample at the channel intersection corners, distorting field lines. For more control of sample injection volume, Jacobson et al. also introduced “pinched injection”, where the potential is applied simultaneously across both of the channels. This injection technique yields higher peak efficiencies and improved RSD values (approximately 0.3%). More sophisticated injection techniques offering finer control of injection volumes and the possibility for sample stacking have also been demonstrated.

Separation efficiencies attained for the initial microfabricated devices were relatively low (less than 100 000 theoretical plates). However, separation efficiencies continue to increase with improvements in wafer design. Alternative separation channel patterns have yielded efficiency values approaching 10⁶ theoretical plates; these include the serpentine and synchronized cyclic CE (four short channels in a square arrangement) designs. In lower resolution, higher throughput purification applications, free-flow electrophoresis has been demonstrated. Several detection methods have been used in conjunction with microchip CE, including UV/VIS absorbance, laser-induced fluorescence (LIF), and mass spectrometry (MS) with an ESI interface. LIF detection is the most widely employed mode of detection for microfabricated devices owing to its high sensitivity and selectivity. Confocal microscopy fluorescence detection offers the possibility of single-molecule detection. The coupling of microchip CE devices with MS is still in its infancy.

Several different CE separation modes have been applied using microchip CE. MEKC of coumarin dyes using sodium dodecyl sulfate (SDS) as the surfactant was demonstrated. The same coumarin dyes were separated also using open-tubular capillary electrophoresis with octadecyl functionalities immobilized on the channel walls. The increased separation efficiencies and decreased analysis times have allowed microchip CE to be applied to the DNA sequencing, genotyping, and the amplification of DNA fragments. Capillary array electrophoresis devices that use up to 12 lanes simultaneously have been applied to the detection of HLA-H variants in the diagnosis of hemochromatosis. Cell lysis and polymerase chain reaction (PCR) amplification, and size-sieving of DNA fragments have been achieved on a single microchip. Research has been developed also to facilitate the detection of DNA mutations on a microchip device.

4 MODES OF CAPILLARY ELECTROPHORESIS

4.1 Free-solution Capillary Electrophoresis

FSCE, or CZE, is the most commonly employed mode of CE owing to its versatility; the applications of FSCE are as widely varying as the composition of
the BGEs. The separation capillary is filled with a predominantly aqueous buffer solution; additives may be incorporated into the BGE to achieve the desired selectivity and resolution of separation. The BGE chosen should demonstrate good buffering capacity and low background current to suppress Joule heating effects. The pH of the BGE can influence both the charge of the analyte and the fused-silica capillary wall according to their pKₐ values. Hence the EOF in the capillary is also influenced. Some buffer additives may influence the solute – capillary wall interactions. The compatibility of FSCE with the aforementioned detection modes (section 3.5) is limited only by interferences from the BGE components. In the normal polarity mode, charged species are separated according to their respective charge-to-mass ratios in an applied electrical field. Cations migrate by coulombic attraction toward the cathode, with thecation of the lowest charge-to-mass ratio migrating fastest. Conversely, anions migrate toward the anode, with those of the lowest charge-to-mass ratio migrating fastest. At a sufficient EOF within the capillary, the coulombic attraction of the anions for the anode will be overcome, and the anions will migrate toward the cathode. Overall, the migration order in FSCE is cations (from high to low charge-to-mass), followed by neutral species (unseparated), and finally anions (from low to high charge-to-mass).

4.2 Micellar Electrokinetic Chromatography

MEKC is one of only two modes of CE that allows the simultaneous separation of charged and neutral analytes. Since its introduction by Terabe et al. in 1984, MEKC has grown dramatically to encompass hundreds of applications. The incorporation of micelles above their critical micelle concentration (CMC) in the BGE creates a pseudo-stationary phase. Differential partitioning of analytes with the micelles results in their differential migration through the capillary, and hence their separation. Since the separation mechanism involves both a partitioning process and electrophoretic migration, MEKC is considered a hybrid separation technique of a partitioning process and electrophoretic migration, stationary phases in MEKC.

Micelles are spherical aggregates of surfactants with hydrophobic tail groups oriented toward the center of the micelle and polar head groups oriented toward the aqueous solution. The number of monomers in a micelle varies from surfactant to surfactant, and the presence of organic solvents in the separation buffer can disrupt micelle formation. The micelles will migrate through the capillary according to their apparent electrophoretic mobility, a function of both the charge-to-mass ratio of the surfactant and the EOF in the capillary. The migration of anionic micelles, such as SDS, opposes EOF in an uncoated capillary at normal system polarity. However, at sufficient EOF (pH > 6), the anionic micelles will migrate toward the cathode, past the detector (Figure 7a). The use of cationic surfactants, such as cetyltrimethylammonium bromide (CTAB), may require reversed system polarity. The cationic surfactant molecules adhere in a bilayer to negatively charged silanol groups at the capillary wall, rendering the capillary surface positively charged (Figure 7b). Nonionic and zwitterionic surfactants can also be utilized, but only in conjunction with charged surfactants. In addition to conventional surfactants, different types of organized media such as dendrimers and ionic polymers have been explored as pseudo-stationary phases in MEKC.

There exists a finite elution window (hence a finite peak capacity) in MEKC, between the time of migration for a neutral solute (such as methanol), tₑₒ, and the time of migration for a completely retained solute (such as the hydrophobic dye, Sudan III), tₑₘ (Figure 7c). For neutral analytes, the capacity factor, k', in MEKC is defined according to Equation (28):

$$k' = \frac{tₑₚ - tₑₒ}{tₑₒ[1 - (tₑₚ/tₑₘ)]}$$  \hspace{1cm} (28)
where $t_r$ is the migration time of the solute. For charged analytes, Equation (28) must be adapted to include the time the analyte migrated in the BGE, $t_0$, (Equation 29):

$$k' = \frac{t_r - t_0}{t_0[1 - (t_r/t_{mc})]}$$  

(29)

Note that as $t_r$ approaches $t_{mc}$, Equations (28) and (29) are reduced to the capacity factor equation for chromatographic separations. Retention indices have been developed for MEKC, analogous to retention indices developed for gas chromatography (GC), to allow the normalization of different micellar systems. The fundamental resolution equation in MEKC is given by Equation (30):

$$R = \left( \frac{N^{1/2}}{4} \right) \frac{\alpha - 1}{\alpha} \left( \frac{k_2'}{1 + k_2'} \right) \left[ 1 - (t_r/t_{mc}) \right] \left[ 1 + (t_{c0}/t_{mc}) k_1' \right]$$  

(30)

where $N$ is efficiency, $\alpha$ is separation selectivity (Equation 23), and $k_1'$ and $k_2'$ are the capacity factors for analytes 1 and 2, respectively. Note that resolution in MEKC decreases significantly as $t_r$ approaches $t_{mc}$.

The pseudo-stationary phase used in MEKC affects analyte selectivity and resolution. Currently, there are many organized media to choose from; usually, the choice is made experimentally. In order to make a more informed selection, Yang and Khaledi have established linear solvation energy relationships, taking into account the relative sizes, polarizability, hydrogen bond donating properties, and hydrogen bond accepting properties of the analytes and the various surfactant molecules. Increasing the micellar concentration above the CMC in the BGE can affect the size of the elution window, but has a negligible effect on analyte selectivity. Buffer additives such as organic solvents, glucose, and urea have been added to the BGE in MEKC in order to extend the elution window, while concomitantly reducing hydrophobic interactions between analytes and micelles and altering analyte selectivities. The incorporation of a cyclodextrin (CD) into the BGE introduces shape selectivity to the MEKC separation mechanism; this is especially useful in the analysis of polycyclic aromatic hydrocarbon (PAH) structural isomers.

SDS is by far the most commonly employed surfactant in MEKC. Owing to the strong hydrogen bond donating properties of SDS, this pseudo-stationary phase is applicable to a wide variety of analytes from caffeine metabolites through DNA adducts to flavonoids. However, SDS micelles demonstrate a practical limit in the analysis of very hydrophobic compounds such as PAHs and steroids. The incorporation of CDs into SDS micellar separation solutions has been shown to increase analyte selectivity (Figure 8a–c). For particularly hydrophobic analytes, bile salts such as sodium glycodeoxycholate and sodium taurocholate are more effective than SDS. Fluorocarbon...
micelles, such as lithium perfluorooctane sulfonate, are also applicable to the analysis of relatively hydrophobic solutes; these pseudo-stationary phases have been applied to a limited extent in MEKC, mostly owing to a lack of availability. Anionic surfactants other than SDS have been applied in MEKC including N-D-gluco-N-methylamidate for amino acids (AAs) and (R)- and (S)-N-dodecyloxycarbonylvaline for chiral separations. Cationic surfactants, such as CTAB, have been applied in the analysis of negatively charged species such as carboxylic acids and nucleic acids. Nonionic and zwitterionic micelles have been applied to the separation of AAs and polypeptides. Mixed micellar separation systems have received a great deal of attention recently. Major advantages include expanded elution windows and alternative selectivities to accommodate the separation of complex analyte mixtures. In contrast to conventional micelles, polymeric pseudo-stationary phases, which can tolerate up to 30% organic modifier in the BGE, have been applied to particularly hydrophobic solutes such as PAHs, fullerenes, and N-alkylphenones. The use of vesicles or the simultaneous use of oppositely charged surfactants (SDS and dodecytrimethylammonium bromide, for instance) has been shown to enhance greatly the elution window and increase solute selectivity.

4.3 Capillary Isoelectric Focusing

Traditionally, the isoelectric focusing of proteins is carried out using SGE. The adaptation of this methodology to the capillary format, first demonstrated by Hjerten and Zhu in 1985, has revealed distinct advantages. cIEF involves the separation of charged analytes, usually proteins or peptides, according to their respective isoelectric points (pI), which is a function of their surface charge. A stable pH gradient is established and maintained in the BGE by the addition of ampholytes, species that contain both basic and acidic functionalities. Analytes migrate through the BGE until they encounter the pH that matches their pI. Ideally, a linear relationship between pI and relative analyte mobility is established (Figure 9a and b). When the focusing of analytes is complete, the current drops to approximately one-fifth of its original value. Nonideally, solutes may interact with the internal capillary surface. The capillary surface may be treated to control such interactions and also the mobility of solutes via EOF. Covalent capillary coatings have been utilized for this purpose. Dynamic capillary wall modification has been achieved in uncoated capillaries by adding methylcellulose (MC) derivatives to the BGE.

After the analyte bands have been focused, they must be detected. In the absence of EOF, two schemes are commonly utilized. The first scheme, chemical mobilization, involves buffer replacement. First, the analytes are focused according to their respective pI values. Once the system has reached a steady state, the inlet and outlet buffer reservoirs containing a highly acidic and a highly basic solution, respectively, are replaced with buffer reservoirs containing an additional counterion (typically Na+ in the inlet and Cl− in the outlet). The presence of the additional ions disrupts the established steady state and the system re-establishes equilibrium to maintain electroneutrality. The analyte molecules reacquire a net charge as the pH of each zone changes. The analyte bands are separated and migrate past the detector. Concomitantly, the current in the capillary increases according to the conductivity of the BGE. Owing to an inherent anodic or cathodic “drift” associated with cIEF, only analytes with pI values between approximately 5 and 9 may be analyzed in conjunction with buffer replacement. Alternatively, negative pressure and voltage may be applied simultaneously in order to maintain focused analyte bands; otherwise, laminar flow introduced hydrodynamically promotes band broadening. Additionally for the detection of focused solutes in the absence of EOF, one can visualize the entire focused solute zone within the capillary using an array detector, or move the capillary itself past a stationary detector. Mobilizing the analyte bands past the detector in the presence of EOF results in faster analysis times. However, the variability of EOF according to the condition of the capillary surface, as well as the pH and ionic strength of the BGE, can lead to nonlinear functions of pI versus analyte mobility and restrict the useful analyte pI range to small intervals. More recent innovations involve analyze zone fraction collection with off-line MALDI/TOF/MS detection and cIEF performed on microchip devices.

4.4 Size-sieving Capillary Electrophoresis

The size-dependent electrophoretic separation of proteins, DNA molecules, and carbohydrates in microbore capillaries offers several advantages over conventional SGE. Reduced quantities of samples, buffers, and gel matrices are required; quantitation is facilitated by online detection (typically LIF or UV/VIS absorbance); the system is more amenable to automation; and faster, more efficient separations are achievable at field strengths up to 500 V cm−1. Owing to the anticonvective dimensions of microbore capillaries, less rigid matrices are required to separate biomolecules in the same size range. Capillary gel electrophoresis (CGE) utilizes chemically cross-linked gels and dynamic size-sieving capillary electrophoresis (DSCE) utilizes entangled polymer
Figure 9 Electropherograms and pH gradient linearity plots for cIEF methods. (a) cIEF with chemical mobilization; (b) cIEF with hydrodynamic mobilization. Peak identification: (1) cytochrome c; (2) ribonuclease A; (3a–c) lentil lectin I–III; (4a, b) myoglobin I, II; (5) carbonic anhydrase I; (6) carbonic anhydrase II; (7) β-lactoglobulin; (8) trypsin inhibitor; (9) amylglucosidase. solutions. Currently, capillary arrays of up to 100 capillaries allow the separation of biomolecules in multiple "lanes" (125).

The electrophoretic mobilities of biomolecules with the same charge per molecular unit are effectively independent of molecular size. Therefore, the addition of a frictional component to the BGE is necessary to achieve size-dependent separations. Two models have been used to describe the separation of biomolecules in SGE, the Ogston sieving model (126) and the reptation model (127). The former applies to the migration of nondeformable, approximately spherical biomolecules through a porous network. For species separated according to the Ogston sieving mechanism, a linear, semilogarithmic "Ferguson plot" can be constructed by plotting data according to Equation (31):

\[ \log \mu_T = - \log \mu_0 - K_R(T) \]  

where \( \mu_T \) is the corresponding electrophoretic mobility of the species at that gel concentration, \( \mu_0 \) is the electrophoretic mobility of the species in free solution, the slope, \( K_R \), is the retardation coefficient, and \( T \) is the percentage gel concentration. \( K_R \) is proportional to \( \left( \frac{r}{R_g} \right)^2 \), where \( r \) is the gel fiber radius and \( R_g \) is the radius of gyration of the species. In contrast, the reptation model describes the "snake-like" migration of relatively larger biomolecules through the separation matrix, with electrophoretic mobilities that are inversely related to molecular size. The biased reptation model (128) and the biased reptation model with fluctuations (129) have been used to account for the concomitant stretching and conformational fluctuations of much larger biomolecules at higher field strengths.

Chemically cross-linked gels employed in CGE have well-defined, rigid pore sizes and relatively high viscosities, resulting in characteristically high separation...
efficiencies. Almost exclusively, polyacrylamide gels (PAGs) have been employed in CGE with acrylamide as the monomer and \(N,N'\)-methylenebisacrylamide as the cross-linking agent. Gel properties are varied by adjusting the percentage of monomer (\%T) and percentage of cross-linking agent (\%C) during polymerization. For mechanical stability, the PAGs are chemically bonded to the capillary wall. Serious limitations of chemically cross-linked PAGs include (i) heat sensitivity leading to bubble formation with the elimination of EOF, (ii) sample contamination by carryover between analyses, (iii) severely limited lifetimes for individual capillaries (usually less than 10 analyses per capillary), and (iv) restriction of sample introduction to electrokinetic injection.

In DSCE, low-viscosity polymer solutions are employed as size-sieving matrices at concentrations above or below the entanglement threshold of the polymer. These matrices possess a highly flexible, dynamic pore structure and may be replaced between analyses to enhance run-to-run reproducibilities. Linear polyacrylamide (LPA) solutions, with zero amount of cross-linking agent, have been used. The use of derivatized agarose gels requires elevated capillary temperatures (i.e. above their gelling temperature) to facilitate the loading of the separation matrix and enhance the separation mechanism. Other polymers have been used as size-sieving matrices in DSCE, including hydroxyethylcellulose (HEC), hydroxypropylmethylcellulose (HPMC), hydroxyethylcellulose (HEC), and poly(ethylene oxide) (PEO). The mixing of different molecular weights of the same matrix and the mixing different matrices have resulted in enhanced separation performance.

Barron et al. demonstrated that a fully entangled network is not necessary for the dynamic size-sieving separation of DNA fragments. Therefore, the Ogston sieving and reptation models that involve a porous network are insufficient descriptors of the separation mechanism in DSCE. As a result, the transient entanglement coupling mechanism was proposed, whereby large biomolecules undergo interactions with multiple size-sieving polymer molecules at any one time as they migrate through the capillary, yielding size-dependent separations (Figure 10). In DSCE, lower concentrations of higher molecular weight polymers are more effective in the separation of larger biomolecules, and high concentrations of lower molecular weight polymers are more effective in the separation of smaller biomolecules.

In DSCE, EOF within the capillary must be eliminated or effectively reduced such that the size-sieving matrix does not electrophorese from the capillary. The elimination of EOF also enhances run-to-run migration reproducibilities. To this end, both covalent and dynamic capillary coatings have been utilized. Alternatively, the surface silanols on the capillary wall may be fully prototated by treatment with 0.1 M HCl. For the analysis of negatively charged biomolecules, it is necessary to use reversed system polarity with the negatively charged electrode (cathode) at the capillary inlet. Other experimental variables may be optimized, including applied field strength and capillary temperature. The migration velocity of biomolecules is directly proportional to the constant, applied field strength. Additionally, potential gradients and pulsed electrical fields have been applied to increase the separation efficiency and resolution and decrease the analysis time in biomolecular separations. Capillary temperature gradients may also be employed in DSCE; higher temperatures result in a decrease in viscosity and an increase in dynamic pore size.
4.5 Nonaqueous Capillary Electrophoresis

Aqueous-based buffer systems have been applied predominantly in CE separations owing to the many favorable characteristics of water and its well established chemical properties. In the mid-1980s, Walbroehl and Jorgenson were the first to report the use of predominantly nonaqueous solvents in CE.\textsuperscript{146} Ten years later, Sahota and Khaledi demonstrated the potential of nonaqueous capillary electrophoresis (NACE) and provided systematic, comparative investigations to aqueous-based systems.\textsuperscript{147} Nonaqueous BGEs can be particularly advantageous in the analysis of relatively hydrophobic compounds. Alternative separation selectivities may be achieved with the use of nonaqueous buffers relative to their aqueous counterparts (Figure 11a and b). In general, higher applied field strengths may be employed in NACE for faster, more efficient separations of improved detectability. The selection of appropriate nonaqueous solvents should include considerations of volatility, solubility of buffer salts and additives, toxicity, reactivity, cost, and flammability. Organic solvents of various chemical and physical properties, including \textit{N},\textit{N}-dimethylformamide, formamide, methanol, ethanol, and acetonitrile, have been utilized successfully in NACE.

To a first approximation, electro-osmotic mobility is directly proportional to the ratio of dielectric constant to viscosity ($\varepsilon/\eta$) of a pure solvent.\textsuperscript{148} A majority of nonaqueous solvents possess comparatively lower $\varepsilon/\eta$ ratios than water, and as a result demonstrate decreased electro-osmotic mobilities. Simultaneously, the zeta potential at the capillary wall may be affected due to a change in the $pK_a$ of the surface silanol groups; this further reduces electro-osmotic mobilities.\textsuperscript{149} Nonaqueous BGEs of higher ionic strengths can be applied for higher sample solubility, sample stacking, and enhanced detectability. Lower currents are generated in nonaqueous solvents so that higher field strengths can be applied without detrimental Joule heating effects; Ohm’s law plots show extended linearity in nonaqueous BGEs.\textsuperscript{147} Analogously, the electrophoretic mobilities of analytes, and hence analyte selectivities, are influenced by the characteristic $\varepsilon/\eta$ ratio of the solvent.\textsuperscript{150} Organic solvents vary in their ability to stabilize ionic species in solution and accept or donate protons. Therefore, organic solvents alter the $pK_a$ values of acidic and basic species; generally, the $pK_a$ values of acidic species are more affected than basic species.\textsuperscript{151} It is important to bear in mind that in nonaqueous systems, $pH$ values of separation media and $pK_a$ values of solutes must be replaced by the appropriate apparent values, $pH^+$ and $pK_a^+$, respectively.

Several modes of detection are compatible with NACE. Direct UV/VIS absorbance detection is most commonly employed, with detection limits generally in the $10^{-5}$ M range.\textsuperscript{149} Limitations exist in the application of LIF detection to NACE owing to the potential of signal quenching in lower viscosity solvents, and also changes in fluorescent excitation and emission wavelengths according to solvent polarity.\textsuperscript{148} The use of nonaqueous separation buffers in combination with solvent evaporation in electrospray ionization mass spectrometry (ESIMS) is particularly beneficial.\textsuperscript{152} Detection limits for NACE in conjunction with ED as low as $10^{-9}$ M have been reported.\textsuperscript{149}

NACE has been applied to several classes of charged solutes, including cationic pharmaceuticals and their metabolites,\textsuperscript{153} metal ions, organic acids,\textsuperscript{154} peptides,\textsuperscript{147} carboxylic acids,\textsuperscript{150} and anionic surfactants.\textsuperscript{155} For the separation of neutral solutes, charged...
additives capable of interacting with the solutes must be employed. To this end, starburst dendrimers and ionic polymers have been utilized. The separation of PAHs by NACE requires charge-transfer or induced-dipole interactions provided by organic cations such as tropylum or phenyl-substituted pyrylium salts (tetrafluorborates and perchlorates). Chiral separations have also been performed in NACE using CDs as the chiral selectors. Such separations can be superior to their aqueous counterparts owing to the increased solubility of CDs in organic solvents and their reduced binding constants with extremely hydrophobic solutes.

4.6 Capillary Electrochromatography

CEC combines the high selectivity and versatility of LC stationary phases with the high efficiency, electrically driven flow of CE. Fused-silica capillaries are packed with stationary phase particles and the mobile phase is transported according to EOF. Neutral or charged solutes are separated on the basis of their differential partitioning interactions between the stationary phase and the mobile phase; charged solutes may also be separated according to their respective electrophoretic mobilities. In the absence of pressure-driven laminar flow, stationary phase particle diameters as small as 0.4 μm may be utilized. As a result, column efficiencies are usually an order of magnitude greater in CEC than in LC. The routine application of CEC to complex separation problems is currently limited by several factors, including the irreproducibility of EOF within the capillary, challenging column preparation, the production of Joule heat within the packed capillaries, and bubble formation within the capillary eliminating EOF. At present, it is unclear as to whether Joule heating within the capillary, inhomogeneous packing of the capillaries, or a combination of the two phenomena leads to bubble formation.

In CE, an electrical double layer forms at the solid/liquid interface of the capillary wall due to the presence of deprotonated silanol groups, producing EOF. In CEC, an electrical double layer is formed at the liquid/solid interface of each stationary phase particle. Theory dictates that EOF is independent of capillary ID if the latter is 20 times larger than the thickness of the electrical double layer. However, the EOF in CEC is highly dependent on several experimental parameters, including characteristics of the capillary wall and stationary phase particles, electrolyte concentration, pH, ionic strength, column temperature, and mobile phase organic modifier content. The complex dependences of these parameters on the EOF result in the inherent irreproducibility of CEC. Additional on-column band broadening contributions exist relative to CE. Owing to the presence of a stationary phase in CEC, resistance to mass transfer and eddy diffusion are encountered in addition to longitudinal diffusion. In terms of off-column band-broadening processes, the column packing procedure and the presence of the frits can be problematic. Rathore and Horvath have investigated discontinuities associated with flow velocity and electrical field strength in CEC.

Column preparation in CEC, including frit formation and column packing, is considered to be an art at this time. The retainting frits are most commonly formed by the sintering of a plug of stationary phase particles, wetted with either water or potassium silicate solution or by in situ polymerization of a potassium silicate solution. They must be mechanically stable and sufficiently porous, and must not promote significant solute band-broadening effects. Stationary phase particles may be packed by slurry techniques, glass drawing, the use of centrifugal force, or electrokinetic migration.

Alternatively, OTCEC can be performed whereby the stationary phase is attached to the inner capillary wall or to channels of microchip devices. The open-tubular format eliminates the eddy diffusion term of the van Deemter equation, but also reduces loadability and retention capabilities. OTCEC has been used in the separation of anions, PAHs and proteins.

A more recent innovation in CEC involves column construction via monolithic or sol–gel polymerization in situ to avoid the problems associated with inhomogeneous packing techniques and potentially problematic frit formation. For instance, N-isopropylacrylamide and 2-acrylamido-2-methylpropanesulfonic acid are copolymerized and cross-linked with N,N′-methyleneacrylamide. Also, monolithic poly(butyl methacrylate–co-ethylene dimethacrylate–co-2-acrylamido-2-methyl-1-propanesulfonic acid) capillary columns have been synthesized and characterized in CEC. Sol–gel, monolithic fabricated OTCEC columns have been constructed forming a porous, high surface area layer on the capillary walls. Using an analogous in situ polymerization process, molecularly imprinted CEC columns may be fabricated. These have proven especially useful in chiral separation applications.

The instrumentation employed for CEC resembles that of CE; however, buffer reservoirs may need to be pressurized in order to reduce bubble formation. Typical run conditions include the application of a potential of 10–50 kV across capillaries with dimensions of 0.5–1.5 m in length and 10–100 μm ID. A detector window is created by removing a 1-cm section of the outer polymide coating of the capillary. For in-column detection, the polymide coating is removed from a packed portion of the capillary; for on-column detection, it is removed from an unpacked portion (Figure 12a). The former can lead to reduced sensitivity in optical detection modes...
owing to background scattering from the particles; the latter can lead to the degradation of peak efficiency due to band broadening after passage through the end frit. Alternatively, a separate portion of capillary tubing containing a burned window may be coupled to the packed capillary using a Teflon® tubing sleeve (Figure 12b). MS appears to be a viable detection scheme for packed CEC owing to the compatibility of mobile phase composition and flow rate (particularly for ESI interfaces) and the relatively higher sample capacities.

A variety of stationary phase materials have been used in CEC to address chiral separations, and the resolution of PAH structural isomers. Figure 13 shows the high-efficiency separation of 16 PAH structural isomers using CEC. Common particle diameters of stationary phase are 1.5–10 µm. The most common stationary phase material is octadecyl-derivatized silica. The choice of mobile phase not only affects analyte selectivity in CEC, but also directly influences the magnitude of EOF. Common organic modifiers in CEC for aqueous-based systems containing electrolyte include methanol, 2-propanol, and acetonitrile. Zare et al. demonstrated gradient elution CEC. In this work, two capillaries were placed in different buffer reservoirs containing different mobile phase compositions. The two capillaries were connected to the separation capillary in a “T” formation. A separate power supply was connected to each mobile phase reservoir and the system was computer controlled to change the mobile phase composition as a function of time.

5 APPLICATIONS

5.1 Amino Acids, Peptides, and Proteins

Most commonly, AA compounds are derivatized with fluorescent labels to enhance their detection in CE. In combination with LIF, detection levels into the zeptomole range have been achieved. The derivatization of charged AA functionalities alters the pK_a values and concomitantly electrophoretic mobilities; hence separation selectivity and resolution are affected. The majority of AA derivatization agents employed for detection in CE were developed originally for detection in LC. These include 3-(4-carboxybenzoyl)-2-quinolinecarboxaldehyde (CBQCA), 4-(dimethylaminooazo)benzene-4'-sulfonyl (DABSYL) chloride, 9-fluorenylchloroformate (FMOC), PTH, NDA, OPA, FITC, dansyl chloride, and fluorescamine. In addition to FSC, MEKC and chiral CE have been applied to the separation of AAs. Figure 14 shows an electropherogram of the MEKC separation of the 20 AAs labeled with PTH. According to the mode of separation employed, the BGE composition may vary greatly and must be optimized according to pH, percentage of organic modifier, and concentration of buffer additives.

The analysis of peptide mixtures is becoming increasingly important owing to their applications in the pharmaceutical industry and other fields. CE has proven...
highly useful in the isolation, purification, protein digest mapping, and structural analysis of peptides. Several detection modes have been employed in conjunction with peptide separations in CE, including UV absorbance (both direct and indirect), LIF, ED, CL, radioactivity, and MS detection. Sample stacking, on-line preconcentration, and ITP preconcentration strategies have enhanced signal-to-noise ratios up to 1000-fold.\(^{(187)}\)

For peptide separations in CE, temperature, capillary dimensions, applied field strength, and BGE composition should be optimized experimentally. Peptides can be separated according to differences in their terminal and side-chain \(pK_a\) values; however, specific \(pK_a\) values for peptides are rarely known. Owing to the charged functionalities of their AA constituents, the CE separation of peptides is influenced dramatically by the pH and ionic strength of the BGE. Additionally, the pH and ionic strength of the BGE alter the EOF in the capillary. The application of high ionic strength BGEs has been shown to enhance peptide separations; however, there is a practical limit due to the possibility of excessive Joule heating. Low-pH BGEs should be avoided as such conditions can cause analyte adsorption in uncoated fused-silica capillaries. In addition to the use of coated capillaries, buffer additives, such as metal ions, ion-pairing agents, and surfactants, have been employed to suppress capillary wall interactions.\(^{(188)}\) These additives may also influence separation selectivities. The addition of organic solvents such as acetonitrile and aliphatic alcohols to the BGE alters the viscosity of the separation medium, and also the solubility and conformation of the peptides. For the enantiomeric resolution of peptides, chiral selectors such as CDs, bile salts, and chiral crown ethers have been utilized.\(^{(189)}\) The impact of peptide hydrophobicity on separation in CE is unclear. Similarly, insufficient data exist concerning the effect of peptide secondary structure on separation in CE. Nonetheless, the \(cis\rightarrow trans\) isomerization of peptides and the dependence of peptide secondary structure on hydrodynamic radius have been investigated.\(^{(190)}\)

SGE is used extensively as a tool in protein chemistry. The transfer of this technology to the capillary format has offered several distinct advantages, including more rapid analyses with higher separation efficiencies, but at the same time has introduced new challenges. Interactions of structurally complex proteins with ionized silanol groups at the capillary wall can cause partial or complete denaturation of the proteins, generating spurious peaks and band broadening. Basic proteins are particularly problematic. Thus, regardless of the CE mode employed (FSCE, cIEF, or SSCE), the chemistry of the capillary surface is a critical experimental parameter. Depending on the concentration of the protein and its sample matrix, ITP preconcentration\(^{(191)}\) or solid-phase

---

**Figure 14** Electropherogram of PTH-labeled AAs with 25 mM phosphate buffer (pH 8.0) containing 50 mM SDS, at 27 kV applied voltage in a fused-silica capillary (70 cm × 50 µm ID). Detection by absorbance at 260 nm. (Reproduced by permission of John Wiley & Sons, Inc. from N.J. Kim, J.H. Kim, K.-J. Lee, *Electrophoresis*, 16, 510–515 (1995).)
affinity purification\textsuperscript{(192)} may be necessary. UV absorbance (190–280 nm) of peptide bonds or AA side-chain functionalities is the most common detection mode. LIF detection has been applied to a significantly lesser extent; both covalently bonded and noncovalently bound fluorescent dyes have been applied.\textsuperscript{(193)} MS detection with a TOF analyzer has proven useful in the confirmation of molecular weights of proteins. Both MALDI/MS and ESI\textsuperscript{MS} have been investigated; however, the former cannot be directly interfaced to the CE instrument at this time.

The strategy chosen for capillary surface modification in protein analysis should reflect the properties of the protein including its pH and post-translational modification chemistry. In high-pH buffers (above the pH for a protein), proteins are negatively charged, causing repulsion at the negatively charged wall. However, the secondary and tertiary structures of proteins are sensitive typically to pH extremes. Also, proteins have less charge diversity under such conditions, reducing the likelihood of their separation. Salts, amines (ranging in size from hydroxylamine\textsuperscript{(194)} to chitosan\textsuperscript{(195)}), surfactants, polyamions, and zwitterions can be added to the BGE to assist in protein separations. These additives compete for negatively charged sites at the capillary wall effectively to eliminate or reverse the direction of EOF. These additives can also form ion pairs with the proteins and alter their electrophoretic mobilities. Neutral polymers such as poly(vinyl alcohol) (PVA),\textsuperscript{(196)} polyethyleneimine (PEI),\textsuperscript{(197)} and cellulose derivatives\textsuperscript{(198)} can be used to coat dynamically the capillary surface and nearly eliminate EOF. Figure 15(a) and (b) demonstrates the effects of a dynamic PVA coating versus a thermally immobilized PVA coating in the CE separation of five proteins. In addition, several chemistries have been proposed for the covalent modification of the capillary wall; the most frequently used covalent wall coating is polyacrylamide.\textsuperscript{(199)} Alternative covalent coatings involve silanization chemistries, or the polymerization of cellulose derivatives, acrylates, and polyimines. Polymeric coatings tend to be more robust with respect to pH.\textsuperscript{(200)}

A multitude of reports have appeared encompassing the separation of several classes of proteins in CE. Only a selected number of protein applications will be addressed here. FSCE has been used to separate charge variants of recombinant DNA-derived proteins,\textsuperscript{(201)} conformational hemoglobin variants,\textsuperscript{(202)} food proteins,\textsuperscript{(203)} antigen–antibody complexes,\textsuperscript{(204)} and microheterogeneous glycoproteins.\textsuperscript{(205)} Lipoproteins may require the addition of surfactants or organic solvents to the BGE to enhance solubility.\textsuperscript{(206)} cIEF has been used to separate monoclonal antibodies,\textsuperscript{(207)} and in conjunction with immunoassays to resolve bound versus unbound antigen–antibody complexes.\textsuperscript{(208)} In SDS/CGE or SDS/DSCE, proteins are denatured with 0.1% SDS and separated according to molecular weight, independent of conformation.\textsuperscript{(209)} Even though this method offers advantages over the traditional sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS/PAGE) technique, both techniques may be supplanted by MS detection in protein molecular weight determinations.

### 5.2 Nucleic Acids and Oligonucleotides

DNA molecules are negatively charged at pH values greater than approximately 4 and migrate accordingly in an applied electrical field. DNA separations are performed typically in aqueous TRIS–borate–EDTA buffer solutions, pH 8.3, to maximize solubility. In CE, the detection of DNA molecules can be achieved based on native UV absorbance at 260 nm, or by LIF. The latter enhances detection selectivity and sensitivity, but typically requires the labeling of DNA molecules with fluorescent molecules.

For the analysis of single-stranded DNA (oligonucleotides), a denaturant such as formamide or urea is added to the separation medium to prevent reannealing and secondary structure formation. The use of chemically cross-linked gel matrices in CGE offers single-base resolution,\textsuperscript{(210)} but the use of low-viscosity, replaceable polymeric matrices in DSCE offers greater convenience and can provide comparable resolving power. In general, low molecular weight polymers are employed
at high concentrations for the separation of small oligonucleotides. Capillary affinity gel electrophoresis has been applied to the separation of oligonucleotides according to size and base-specific recognition.\(^{211}\)

DNA sequencing of oligonucleotides is a rapidly growing application in CE.\(^{212–214}\) The Sanger dideoxy base labeling chemistries, separation mechanisms, and methodologies currently employed in CE originated in SGE. The most desirable methodology involves a four-dye labeling scheme in a single capillary and the application of a ratio-based base-calling algorithm.\(^{215}\)

High “read lengths” and fast single-base resolution separations are necessary to attain the throughput necessary to accomplish the goals of the Human Genome Project. Although LPA is the most frequently used separation matrix for DNA sequencing applications, the advantages of PEO with various molecular weight ranges has been demonstrated.\(^{216}\) Several formats for the multiplexing of capillaries in conjunction with DNA sequencing have been investigated, including capillary arrays of up to 100 capillaries, sheath-flow designs, and micromachined channels. Figure 16 shows four-color

---

**Figure 16** Four-color M13 DNA sequencing traces analyzed from a microchip CE device. Separation was performed on a 7-cm long channel with a 100-µm twin-T injector using 4% LPA as the separation medium at 40°C. Separation was performed with a voltage of 160 V cm\(^{-1}\) and the detector was 6.5 cm from the injector. Only 2 µg of DNA template were employed per reaction, and 1 µL of the final reaction solution (33%) was loaded on the microchip device. The run was complete in 20 min. (Reproduced with permission of the American Chemical Society from S. Liu, Y. Shi, W.W. Ja, R.A. Mathies, *Anal. Chem.*, 71(3), 566–573 (1999). Copyright 1999 American Chemical Society.)
DNA sequencing utilizing DSCE on a microfabricated (microchip) device. Chang and Yeung have implemented coaxial optical fibers for fluorescence excitation with an argon ion laser and detection using a CCD camera. Extension to a greater number of capillaries in an array may require the use of a charge-injection device (CID). The CID is analogous to the CCD, as a solid-state imaging device, but provides more flexibility in detection schemes and less dark current for enhanced detection sensitivity.

The separation and detection of double-stranded DNA fragments (particularly PCR products and restriction fragments) have been facilitated by the incorporation of various fluorescent dyes in the separation matrix, such as oxazole yellow (YO) (commercially available as YO-PRO-1), oxazole yellow homodimer (YOYO), thiazole orange homodimer (TOTO), and ethidium bromide. These molecules intercalate between DNA base pairs to (i) stiffen the molecules, (ii) increase their positive charge, and (iii) increase their separation resolution. For the separation of DNA fragments between 1000 base pairs and 1.6 megabase pairs in length, the applied field strength can be alternated in its direction and frequency as a function of time. This periodic variation of the applied field strength, or field inversion, forces the DNA molecules to reorient continuously as they migrate through the capillary; the extent of this effect is a function of the DNA fragment length and the applied electrical field. Figure 17(a) and (b) shows the dramatic enhancement of the separation of the 1-kbp DNA ladder standard using field inversion versus the use of constant field in DSCE. Using video microscopy to monitor HEC size-sieving solutions, Morris et al. found that DNA molecules alternate between compact and extended conformations as the field strength is cycled.

More recently, DSCE has been applied to the separation of DNA plasmid molecules: naturally occurring circular double-stranded DNA molecules that replicate independently of the genome. Plasmids may adopt several conformations, including positively or negatively supercoiled, open-circular (either the relaxed form or the nicked form), and linear conformations. The electrophoretic mobility of DNA plasmids is highly dependent on the separation conditions employed, such as the BGE and the applied field strength. In addition, the majority of plasmid DNA separations have been performed in the presence of DNA intercalating dyes. As a result, differences in the migration order of conformers have been reported. DNA intercalators can provide high sensitivity in conjunction with LIF detection and enhanced electrophoretic separations of double-stranded DNA fragments. However, their presence may induce undesirable structural changes in plasmid DNA molecules, including stretching and the partial unwinding of DNA.

![Figure 17](image-url) Comparison of field inversion CE and constant field separation. (a) Separation of the 1-kbp DNA ladder at a constant field of \(81\ \text{V cm}^{-1}\). (b) Separation of the same sample with field inversion at 50 Hz with \(E_f = 243\ \text{V cm}^{-1}\) and \(E_b = 81\ \text{V cm}^{-1}\). Conditions: 1 x TBE buffer containing 1% hydroxypropylcellulose, 10\(\mu\)M ethidium bromide in a 100-\(\mu\)m ID coated capillary at 25 \(^\circ\)C. Peak identification of DNA fragments in base pairs: (1) 134; (2) 154; (3) 201; (4) 220; (5) 298; (6) 344; (7) 396; (8) 506; (9) 517; (10) 1018; (11) 1636; (12) 2036; (13) 3054; (14) 4072; (15) 5090; (16) 6108; (17) 7126; (18) 8144; (19) 9162; (20) 10180; (21) 11198; (22) 12216. (Reproduced by permission of John Wiley & Sons, Inc. from C. Heller, C. Pakleza, J.L. Viovy, *Electrophoresis*, 16, 1423–1428 (1995).)
of the DNA double helix, and also the reduction or reversal of the supercoiling orientation.

5.3 Carbohydrates

Carbohydrates are ubiquitous to numerous mechanisms in cellular biology; their structural diversity, including branching and optical activity, reflects their unique functions. FSCE, CGE, DSCE, MEKC, CEC, and chiral CE have been applied to the analysis of carbohydrates. Their separation and detection represent a challenge in CE owing to their charge neutrality (in some cases) and lack of absorption of UV or VIS light. Therefore, as analytes in CE, they often require chemical derivatization for the introduction of detectable chromophores and charged functionalities. Additionally, carbohydrates may vary widely in structural complexity, from simple mono-, oligo-, and polysaccharides, to glycopeptides, glycoproteins, and glycolipid oligosaccharides. Sample isolation and preparation techniques should be chosen judiciously as they may influence the CE separation.

The use of alkaline borate-containing BGEs enhances the UV absorbance detection of carbohydrates at 195 nm, and simultaneously introduces negative charges to the molecules through complexation. For AA-containing carbohydrates such as glycoproteins and glycopeptides, direct UV absorbance detection may be employed. LIF detection has proven to be a valuable tool in the analysis of fluorescently labeled carbohydrates, achieving single-molecule detection levels in some instances. The inherently poor sensitivity characteristic of indirect detection for carbohydrates, either UV/VIS absorbance or fluorescence, can be enhanced significantly by the use of a laser light source. Both helium–cadmium lasers (325 or 442 nm) and argon ion lasers (488 nm) have been utilized for this purpose. Both electrochemical and RI detection of carbohydrates have been demonstrated with femtomole detection levels and linearity over three orders of magnitude of concentration. MS detection with ESI sample introduction and various mass analyzers has allowed the simultaneous structural characterization of carbohydrates. MALDI/MS in conjunction with fraction isolation by CE has proven useful in the elucidation of carbohydrate branching and molecular weight; future applications may involve the direct coupling of MALDI/MS with CE.

In order to enhance detection sensitivity, and in some instances improve separation selectivity, carbohydrates have been derivatized chemically. Owing to varied and/or incomplete reactivities of native hydroxyl functionalities, reductive amination followed by reaction with an amine-selective reagent, such as 2-aminopyridine, generates negatively charged analytes in neutral and alkaline pH buffers with a suitable chromophore. Unfortunately, contaminating amines can be derivatized, interfering with detection. The fluorescent label 8-aminoanthracene-1,3,6-trisulfonic acid reacts with carbohydrates by Shiff base formation. Figure 18(a–c) demonstrates the effects of various fluorescent labels on the separation of a dextran sample in FSCE. CBQCA has been used in conjunction with LIF detection and PAG-filled capillaries to achieve subattomole detection levels.

Being either neutral or negatively charged, the adsorption of carbohydrates to the capillary wall is less problematic than with other macromolecules such as proteins. However, capillary surface modification has been shown to increase the resolution of carbohydrates. Buffer additives such as polyamines, denaturants such as urea, or ion-pairing agents such as tetrabutylammonium phosphate can invoke secondary equilibria effects and consequently alter the electrophoretic mobilities of the contaminants.

Figure 18 Influence of the fluorescent tag on the separation of a dextran standard with an average molecular weight of 18300. The reagents used were (a) 2-aminopyridine, (b) 5-aminoanthracene-2-sulfonate, and (c) 8-aminoanthracene-1,3,6-trisulfonate. Conditions: voltage, 500 V cm⁻¹ (10 μA); buffer, 0.1 M borate–TRIS at pH 8.65; capillary effective length, 35 cm. (Reproduced with permission of the American Chemical Society from M. Stefansson, M. Novotny, Anal. Chem., 66(7), 1134–1140 (1994). Copyright 1994 American Chemical Society.)
carbohydrate molecules. Ionic surfactants can bind to chemically derivatized celluloses,\textsuperscript{[231]} and highly charged heparins can be partially neutralized by ion pairing with polycationic additives.\textsuperscript{[234]} CDs can be used as buffer additives in CE to disrupt the undesirable formation of carbohydrate micelles in solution.\textsuperscript{[235]}

Glycosaminoglycan (GAG) and carboxylated or sulfated polysaccharide compounds are less difficult to separate and detect in CE owing to their inherent negatively charged sulfate groups and their absorption of UV light at 232 nm. The resolution and efficiency of these carbohydrates in FSCE and MEKC can be enhanced by suppressing EOF in the capillary with the use of an acidic BGE. In the size-sieving mode, DSCE is preferred to CE owing to the large size of the carbohydrate molecules.\textsuperscript{[234]} A highly viscous polyacrylamide solution was especially useful for the separation of the negatively charged, highly polydispersed polysaccharide hyaluronic acid.\textsuperscript{[236]} Surfactant-containing BGEs can be applied in MEKC for the simultaneous separation of sulfated and nonsulfated GAGs.

The mapping, sequencing, and isomeric resolution of glycoprotein glycans have received attention recently. Varied substitution of oligosaccharide chains on the same polypeptide results in different glycoforms. Two- and three-dimensional CE separations may be necessary to resolve glycoprotein glycans.\textsuperscript{[237]} Their sialic acid functionalities should be removed enzymatically prior to separation as these charged functionalities may be lost randomly during derivatization.\textsuperscript{[238]} Peptides and proteins should be removed using alcohol precipitation or chromatographic techniques, or by the incorporation of surfactants in the BGE to simplify electropherograms.

### 5.4 Chiral Separations

Chiral enantiomers (racemates) exist as a mixture of compounds similar in structure but potentially dissimilar in function. Enzymatic reactions that occur in biological systems are stereospecific; a particular enantiomer may be preferred for maximum efficacy. Another enantiomer may be inactive or even highly toxic. Enantiomers of a chiral molecule display optical activity, differing only in the direction in which they rotate plane polarized light. In general, \( n \) chiral centers generate \( 2^n \) enantiomers. From a separation science standpoint, the resolution of chiral enantiomers can present a formidable challenge. In the past several decades, GC and, more commonly, LC have been applied to the separation of enantiomers. Since Zare et al. demonstrated the first chiral CE separation in 1985,\textsuperscript{[239]} numerous reports of chiral separations have appeared in the CE literature. Chiral CE presents several advantages over chiral LC, including versatility in method development, reduced quantities of buffer volumes, chiral selectors and samples, and higher separation efficiencies. Additionally, CE may be used to measure chiral complexation constants and probe new chiral selectors for subsequent use in chromatographic applications.

Several classes of chiral selectors have been explored in CE; many of these chiral selectors were developed initially for chromatographic separation regimes. Chiral selectors differ in mechanism, hence they differ in enantioselectivity for various classes of compounds. Differential complexation of each enantiomer with a chiral selector that is dissolved in the BGE, or immobilized in a gel network or on a chromatographic support, is responsible for enantiomeric resolution. Key characteristics of CE chiral selectors include their stability and solubility in predominantly aqueous-based BGEs, low absorbance in the UV/VIS range, and multiple and varied chemical functionalities for a minimum of three noncovalent, stereospecific interactions with racemates.

Investigations have been performed in order to optimize the composition of the BGE for chiral separations. In general, the higher the binding constant between a chiral selector and an enantiomer, the lower is its required concentration in the separation system. Obviously, the pH of the BGE influences the degree of ionization of the analytes and the chiral selector, hence, the pH of the BGE influences enantioselectivity. The ionic strength of the BGE influences both the EOF and electrophoretic mobilities via the zeta potential at the capillary wall. If the ionic strength does not exceed levels that can cause additional Joule heating, sample stacking may be utilized. The presence of organic solvents in the BGE can alter binding constants and CMCs, extending the usefulness of chiral CE to more hydrophobic racemates.\textsuperscript{[240]} Predominantly non-aqueous BGEs have also been used; the separation mechanisms between chiral selectors and racemates in nonaqueous buffer systems are not as well understood as in aqueous-based systems.\textsuperscript{[157]} Organic cationic buffer reagents and cellulose-based buffer additives have been added to the BGE in order to reverse or suppress the EOF, thereby increasing enantiomeric resolution.

CDs and their derivatives are the most widely applicable class of chiral selectors. CDs are cyclic oligosaccharides with D-glucose units linked via \( \alpha-(1,4') \)-glycosidic bonds; \( \alpha-, \beta-, \) and \( \gamma- \) CDs contain six, seven, and eight D-glucose units, respectively. The interior portion of each truncated-cone molecule is hydrophobic in nature, allowing the hydrophobic inclusion of enantiomers. Hydroxyl groups on the rim of each structure are polar in nature, promoting hydrogen bonding and dipolar interactions with enantiomers. The structure of \( \beta- \) CD is shown in Figure 19(a). Native CDs\textsuperscript{[241]} or CDs derivatized with charged carboxyl, succinyl, and sulfate functionalities\textsuperscript{[242]} have been applied. The use of derivatized CDs allows the
simultaneous separation of neutral and charged species, enhances resolution and selectivity, and alters the migration order of analytes. Electrostatic interactions may be introduced by changing the degree of ionization of the derivatized CD substituents according to the pH of the BGE. Similarly, both charged polysaccharides (heparin, sulfated dextran, and sulfated chondroitin) and neutral polysaccharides (maltodextrins, maltoligosaccharides, dextrins, and dextrans) have been employed as chiral selectors in CE, albeit the binding constants of polysaccharides with racemates can be 1000-fold lower than for CDs. The macrocyclic chiral crown ether 18-crown-6-tetracarboxylic acid has been used to resolve organic and inorganic cationic enantiomers. This polyether contains six oxygen atoms inside the ring for hydrogen bonding and dipolar interactions with racemates.

Armstrong et al. first demonstrated the use of macrocyclic antibiotics for chiral separations in CE. The “basket-like” morphologies of these chiral selectors and their multitude of functionalities and stereogenic centers are responsible for their unprecedented enantioselectivities reported for hundreds of ionic and neutral racemates. Owing to their structural complexity, the optimization of experimental conditions using macrocyclic antibiotics involves a complex function of pH, ionic strength, and organic modifier content of the BGE. The chemical structure of the commonly employed multicyclic antibiotic chiral selector rifamycin B is shown in Figure 19(b). Recently, the macrocyclic alkaloid D-(+)-tubocurarine has been characterized and applied to the chiral separation of organic carboxylates.

Proteins such as α₁-acid glycoprotein, bovine serum albumin (BSA), and orosomucoid have been used as chiral selectors in FSCE, immobilized in a gel matrix, or covalently bonded to a solid support in CEC. The secondary and tertiary structures of proteins influence their enantioselectivity, restricting the pH, ionic strength, and organic modifier content of the BGE that may be employed. Additionally, proteins can be problematic as chiral selectors owing to their strong noncovalent interactions with certain solutes and the capillary wall (reducing separation efficiencies), and also their background absorbance of UV light.

Finally, the combination of chiral CE and MEKC can generate a powerful separation tool. In chiral MEKC, natural or synthetic chiral surfactants are added to the BGE at concentrations above their CMCs. Natural, hydroxylated bile salts such as sodium cholate (Figure 19c) and its derivatives are ionized at relatively low pH, and are particularly useful for the resolution of aromatic racemates containing basic functionalities. Synthetic chiral surfactants such as N-dodecylxyloxacarbonylvaline (Figure 19d), with a polar AA “head” group and a hydrophobic “tail” group, are particularly useful for the separation of relatively hydrophobic enantiomers. Polymer surfactants do not possess a CMC; therefore, they may be used in conjunction with higher percentages of organic modifier in the BGE, especially for hydrophobic enantiomers.

5.5 Inorganic Ions

Traditionally, ion-exchange chromatography, ion-selective electrodes, and atomic absorption spectroscopy have
been applied to the analysis of inorganic ions. More recently, FSCE with indirect UV/VIS absorbance detection has become an alternative method in the analysis of inorganic ions. Applications in the analysis of ions by indirect UV/VIS absorbance detection span several areas, including the pharmaceutical industry, (251) environmental samples, (252) and the paper industry. (253) A chromophore with the same charge and comparable electrophoretic mobility to the analyte ions is added to the BGE. Ideally, the analyte ions should exhibit minimal absorbance at the detection wavelength. The limit of detection is independent of chromophore concentration; however, chromophore concentrations of 1–10 mM are employed commonly to achieve linearity over three orders of magnitude.

The EOF should be in the same direction as the electrophoretic mobilities of the analytes of interest in order to reduce the time of analysis and enhance migration time reproducibilities. (254) Therefore, in the FSCE analysis of anions, a positively charged surfactant is added to the BGE in order to reverse the EOF. Analyte selectivity is influenced by the chemical properties of the surfactant and its concentration. (255)

Chromate is the most commonly employed chromophore, exhibiting absorbance from 200 to 400 nm. For enhanced detection sensitivity, the chromophore pyromellitic acid has been employed. (257) Other chromophores include naphthalene sulfates, (258) benzoate, (259) and ribonucleotides for polyphosphonates and polyphosphates. (260) Tetracyclithrimethylammonium bromide (TTAB) is the most commonly employed EOF reversal agent, but demonstrates limited detectability for bromide ion. Therefore, for samples containing bromide ion, tetracyclithrimethylammonium hydroxide has been employed. (261) The capillary walls may be dynamically or covalently coated to reverse the EOF. (262, 263) Additionally, one or more co-ions may be added to the BGE for buffering purposes and to promote sample stacking. (264) Some inorganic anions such as chloride, bromide, iodide, chromate, thiocyanate, molybdate, tungstate, arsenate, nitrate, and nitrite are detectable in the low-UV region from 180 to 200 nm. (265) The direct UV/VIS absorbance detection of inorganic anions must involve a non-absorbing co-ion. For both indirect and direct UV/VIS absorbance detection of anions, limits of detection are approximately in the micrograms per liter range.

For the analysis of inorganic cations, the addition of EOF reversal agents to the BGE is not necessary. However, anionic and neutral complexing agents such as EDTA, glycolic acid, tartaric acid, citric acid, succinic acid, and 18-crown-6 can be added to alter analyte selectivities. Typically, the concentrations of these agents are a function of their electrophoretic mobilities and complexation constants. Imidazole is the most universal chromophore for cation analysis. (266) Direct UV/VIS absorbance detection may be used for cations after complexation with 8-hydroxyquinoline-5-sulfonic acid. (267) Quang and Khaledi developed a computer model to facilitate the multiparameter optimization of separations involving complexation agents. Their model could be used to simulate and predict the electrophoretic mobility of metal cations as a function of the pH and composition of the BGE. (268)

Anions and cations have been detected simultaneously using 4-aminopyridine as the chromophore; anions and cations approach a centrally located detection window from opposite directions of the same capillary (Figure 20). (269) In addition to direct and indirect UV/VIS absorbance, indirect fluorescence, (270) MS, (271) electrochemical, (272) and suppressed or non-suppressed conductivity (273) detection have been applied to the analysis of inorganic ions in CE. For conductivity detection, a tradeoff exists between sensitivity and symmetrical peak shape; distinct differences in conductivity but similar electrophoretic mobilities must exist for the analytes relative to the co-ion. Conductivity detection of inorganic ions can achieve relatively lower detection limits (nanograms per liter) in conjunction with sample stacking.

The word “chiral” is derived from the Greek word “cheir”, which means hand. Chiral molecules are molecules that are related to each other in the same way that a left hand is related to a right hand. These molecules are mirror images of each other and are nonsuperimposable. Chiral separations have been considered among the most difficult of all separations since enantiomers have identical chemical and physical properties in an achiral environment. In this chapter we will focus on techniques used in high-performance liquid chromatography (HPLC). Most chiral separations by HPLC are accomplished via direct resolution using a chiral stationary phase (CSP). In this technique a chiral resolving agent is bound or immobilized to an appropriate support to make a CSP, and the enantiomers are resolved by the formation of temporary diastereomeric complexes between the analyte and the CSP. Various types of CSPs have been developed, including ligand exchange, protein-based, carbohydrate-based, Pirkle-type, cyclodextrin-based, and macrocyclic antibiotic-based CSPs.

Ligand exchange phases are used with aqueous buffer mobile phases in which enantiomers are separated based on the differences in their charge and ionization constants. Limitations are that only ionized analytes can be separated using this technique and the copper-salt containing mobile phases used absorb in the ultraviolet (UV) region, decreasing detection sensitivity. Protein-based CSPs comprise a number of commercially available columns. These CSPs can be used in the reversed-phase mode with aqueous buffers and there are a limited number of variables to control in developing a separation method. Advantages of protein-based CSPs include low column capacity, limited solvent options and the inability to reverse the elution order of the analyte. The carbohydrate-based CSPs consist of derivatized cellulose and amylose phases and are generally used in the normal phase mode, with the exception of two derivatized phases which are conditioned for the reversed-phase mode. The main disadvantages of these phases are the limitations in pressure and solvent used since these phases are not covalently bonded but merely adsorbed on the silica. These phases may not be used with solvents of intermediate polarity, for example, methylene chloride, acetone, tetrahydrofuran, and acetonitrile. The Pirkle-type CSP typically uses nonpolar organic mobile phases such as hexane, with 2-propanol or ethanol as organic modifiers. Under these conditions, retention of the solutes decreases as the mobile phase polarity increases, following the normal phase mode behavior. The Pirkle-type columns are generally employed in separating compounds containing a π-acid or π-basic moiety, or both. The cyclodextrins can be used with either aqueous buffers or in the polar organic mode. Generally analytes separated using the cyclodextrins require formation of an inclusion complex with the cyclodextrin. Separation is most favorable when the analyte interacts with the mouth of the cyclodextrin molecule via hydrogen bonding to the functional groups present. The
macroyclic antibiotics can be used in either the reversed-phase or the normal phase mode. Enantioselectivities in each mode have been shown to be different. Furthermore, the macrocyclic antibiotics can be derivatized to alter their selectivity. The bonded macrocyclic antibiotic CSPs resemble the protein-based CSPs in many ways. However, the macrocyclic antibiotic CSPs are more stable and have greater capacities than the protein-based CSPs. Numerous analytes are separated using this class of CSP.

1 INTRODUCTION

Chiral separations are important in many scientific disciplines such as chiral synthesis, mechanistic studies, catalysis, kinetics, biology, pharmacology, medicine, and biochemistry. The importance of stereochemistry has long been known, being first recognized more than 100 years ago by Pasteur and van’t Hoff-LeBel.\(^1,2\) In the early 1800s Pasteur achieved the first chiral resolution of a racemic mixture into optical isomers. Using no more elaborate equipment than a microscope and tweezers, he separated the “right-handed” crystals of ammonium tartaric acid from the “left-handed”. The word “chiral” is derived from the Greek word “cheir”, which means hand.\(^3\) Chiral molecules are molecules that are related to each other in the same way that a left hand is related to a right hand; that is these molecules are mirror-images of each other and are nonsuperimposable (see (1) and (2)). The most common example of a chiral molecule is one that possesses a tetrahedral carbon (also known as a stereogenic center) with four different substituents. However, this is not the only requirement for a molecule to exist as chiral. Atoms other than carbon such as nitrogen, sulfur, phosphorus, etc. can also create chirality as well as molecules that lack a reflection symmetry. Structures (3–6) are examples of chiral molecules.

Molecules with different spatial arrangement of atoms may be classified as either diastereomers or enantiomers.\(^4\) The term chiral and enantiomers are related in that enantiomers occur only with compounds whose molecules are chiral, that is, left- and right-handed. Diastereomers are stereoisomers which contain one or more asymmetric centers that are not enantiomers of each other. Two stereoisomers cannot be both diastereomers and enantiomers concurrently. Diastereomers have different chemical and physical properties. They can be distinguished from one another by a number of techniques that take advantage of these different properties. Enantiomers, on the other hand, have identical chemical and physical properties. The only difference is that enantiomers rotate plane-polarized light in opposite directions and interact differently in a chiral environment. Traditionally, chiral separations have been considered among the most difficult of all separations. This is because most conventional separation techniques such as distillation, crystallization, and liquid–liquid extraction, are based on differences in chemical and physical properties of the analytes. The separation of enantiomers is a challenging problem from both theoretical and experimental approaches.

The intense interest in enantiomeric separations emerges not only from pure scientific curiosity. Government guidelines regulating the development of new drugs mandate efficient methods for the analysis and preparation of enantiomerically pure compounds. Nature’s well-known ability to produce and convert chiral compounds with remarkable stereospecificity has been fascinating and led to the study of stereochemical composition of chemical compounds and their pharmaceutical importance. The effect of chiral molecules on the reaction mechanism has long been studied by spectroscopists and organic chemists. Examples of enantiomeric resolutions (resolving stereochemical composition of chiral compounds) can be found in physiological reactions. For example, catecholamines epinephrine and norepinephrine, which are synthesized in the human body mostly by the adrenal medulla, are endogenous hormones that are important in the regulatory processes such as blood pressure, metabolism, and fight-or-flight response.\(^5\) The biochemical synthesis of catecholamines begins with an amino acid tyrosine, which is converted to L-DOPA (3-(3,4-dihydroxyphenyl)alanine). L-DOPA is then converted to L-DOPA decarboxylase, a stereospecific enzyme affecting only the L-enantiomer, to dopamine.\(^6\) Then, another stereospecific enzymatic hydroxylation converts
dopamine into the chiral compound norepinephrine and subsequently to epinephrine by N-methylation. L-DOPA is administered to patients suffering from Parkinson disease to increase the blood level of dopamine in these patients.(6,7) The importance of the correct configuration is also evident from the fact that the naturally occurring \( R \)-epinephrine is at least 20 times more active than its enantiomer. Likewise, \( R \)-(–)-isopropyl norepinephrine is approximately 800 times more effective at the \( \beta_2 \) receptor as a bronchodilator than its enantiomers.(2)

1.1 General Considerations for Chromatographic Stationary Phases

Since the two forms of enantiomers have identical chemical and physical properties in an achiral environment, separating chiral compounds requires a different approach. The new approach to obtain chiral separations is to create a “chiral environment”, which provides more specific interactions between chiral selector-chiral analyte than is obtainable in conventional techniques. Chromatographic methods such as HPLC, thin-layer chromatography (TLC), and gas–liquid chromatography (GC), offer distinct advantages over conventional separation techniques.(8) These methods show promise in moderate-scale separations, offering substantial increases in efficiency. In this chapter we will focus on techniques used in HPLC.

There are four separation modes in HPLC.(9) These include liquid–liquid chromatography, liquid–solid chromatography, size-exclusion chromatography, and ion-exchange chromatography. The most important and commonly used mode in HPLC is liquid–solid chromatography. The support generally employed is specially treated, size distribution-controlled silica. The separation occurs due to differences in retention of various compounds on the stationary phase. The stationary phase can be divided into two large categories: partition chromatography and adsorption chromatography. In partition chromatography the stationary phase used is a liquid, whereas in adsorption chromatography a solid is utilized as a stationary phase. The use of bonded organic phases for HPLC, which will be discussed later in this chapter, has blurred this distinction between partition and adsorption chromatography.

While there are various ways to separate chiral compounds, the common denominator among the available techniques is to create a chiral environment, in which the individual enantiomers can interact differently. It is therefore necessary to employ a chiral resolving agent (commonly called chiral selector) in separating chiral compounds. The use of chiral selectors can be divided into two broad categories: techniques that involve a chiral additive in the mobile phase and techniques that use a CSP, which is immobilized either directly in the column or immobilized on an appropriate support.(10) Another possibility is indirect separation where the analyte is derivatized prior to separation with a chiral reagent to produce diastereomers, which can be separated via achiral chromatographic methods. We will focus on direct resolution of enantiomers.

1.2 General Considerations for Mobile Phase Parameters

Mobile phase selection must be given careful consideration in HPLC. The degree of chemical purity should be seriously taken into consideration since solvent contamination can cause a variety of problems ranging from sensitivity, detection, and resolution, to name but a few. Particulates present in the solvent must be removed, for example by filtration. Also, when using aqueous solvent system such as buffers, bacterial contamination must be addressed. Furthermore, dissolved gases in the solvent can lead to problems with pumps and detectors. Dissolved oxygen, in particular, can cause detection problems, resulting in nonreproducible changes in absorbance when using a UV detector at low wavelengths (210 nm).(9) Additionally, it is crucial to select a mobile phase that is compatible with the stationary phase. Highly basic or acidic solvents, for example, can attack the silica support and destroy the packing of the column.

Other considerations in selecting a mobile phase in HPLC include solubility and polarity. The mobile phase selected must be able to dissolve the analyte and not allow the analyte to precipitate in the column. For example, a sample of protein dissolved in an aqueous buffer at a pH near its isoelectric point tends to be least soluble. Selecting a suitable composition of the mobile phase depends on the type of chiral reagent employed in the separation. When a chiral counterion is used such as in ion-pair chromatography, a mobile phase of low polarity such as methylene chloride is generally used to promote ion-pair formation.(8) On the other hand, when serum albumin is used as a chiral agent, the more appropriate choices for a mobile phase are aqueous solvents with phosphate buffers.

Viscosity is another factor to address when choosing between two mobile phases of similar polarity. Lower viscosity solvent tends to cause less pressure drop in the column, resulting in a greater degree of permeability through the stationary phase.(9) The less viscous mobile phase generally results in a faster separation time. The retention of the analyte in the column also can be increased or decreased by adjusting the concentration of the counterion or by adding a modifier. Adding a polar modifier such as 1-pentanol to the mobile phase will usually result in reduced stereoselectivity.
2 CHIRAL MOBILE PHASE ADDITIVES

One approach to provide a chiral environment is to add a chiral reagent to the bulk mobile phase.\(^{(11,12)}\) Interestingly, many of the compounds used to synthesize the various CSPs were originally used as chiral mobile phase additives in TLC. The separation of chiral compounds by HPLC using a chiral selector in the mobile phase is based on the transient formation of diastereomeric complexes between the chiral selector and enantiomers of the analyte. The differences in the stability of the diastereomeric complexes, their solvation in the mobile phase, or binding of the diastereomeric complexes to the solid support, lead to differences in retention time. Generally, the enantiomer that forms the weakest diastereomeric complex will elute first, whereas the more stable complex will be retained in the column longer and will elute last.

The advantages of chiral mobile phase additives with respect to CSPs are the chiral selector added to the mobile phase can be easily changed; separations are less expensive since conventional achiral stationary phases are used; and a wider variety of chiral selectors are available as mobile phase additives than are available as CSPs. From a developmental standpoint, potential chiral selectors are much more readily investigated as a mobile phase additive than as a new CSP due to the difficulty and cost involved in synthesizing a CSP. Disadvantages associated with chiral mobile phase additives include interference with detection or recovery of the analyte, as well as impurity in the chiral additive can complicate the analytical separation.

In this chapter we will mainly focus on CSPs, their properties and structure, their applications, and the mechanism of separation.

3 CHIRAL STATIONARY PHASE BASED SEPARATIONS

Most chiral separations by HPLC are accomplished by direct resolution using a CSP. In this technique a chiral resolving agent is bound or immobilized to an appropriate support to make a CSP, and the enantiomers are resolved by the formation of diastereomeric complexes between the analyte and the CSP. Various types of CSP have been developed, including ligand exchange, the protein-based, carbohydrate-based, the Pirkle-type, cyclodextrin-based, and the macrocyclic antibiotic-based CSPs. Although each CSP is able to separate a variety of enantiomers, the application of each CSP is typically limited to structurally related chiral compounds. Table 1 gives an overview of the classes of HPLC CSPs.

4 LIGAND EXCHANGE

Among the earliest reports of chiral separations by LC were based on work done by Davankov et al.\(^{(13)}\) using ligand exchange. Davankov et al. developed the first practical approach for resolution of amino acids in LC. These types of columns are available from Phenomenex (CA, USA), J.T. Baker (NJ, USA), and Regis Technologies, Inc. (IL, USA). Davankov et al. attached a chiral bidentate ligand, for example, proline or hydroxyproline, to a support, and added Cu\(^{2+}\) to the mobile phase as shown in Figure 1. Ligand exchange is a retention mode in which enantiomers are separated based on the differences in their charge and ionization constants.\(^{(14)}\) Only ionized analytes can be separated by use of this technique. This type of chromatography

involve the reversible formation of a metal complex by coordination of substrates, and that act as ligands to the metal ion. Ligand exchange chromatography takes advantage of the ability of Cu$^{2+}$ or other divalent metal ions to form diastereomeric complexes with chiral analytes. The complexes should be kinetically labile; that is, the association–dissociation time of the complexes should be faster than the chromatographic timescale. The separation of the enantiomers using this method is based on the difference in thermodynamic stabilities between the enantiomers and a divalent cation. The complex stability is highly dependent on the transition metal used. Cu$^{2+}$ complexes are generally more stable and are preferable for HPLC than Ni$^{2+}$ or Co$^{2+}$ complexes, which are used more prevalently in gas chromatography (GC). Other racemates that can act as bidentate ligands, such as $a$-hydroxy carboxylic acids, can be resolved using this method. The selectivity and efficiency of this type of separation are greatly affected by pH, ionic strength of the mobile phase, and temperature.

Some of the drawbacks using the ligand-exchange approach is its limitation to chiral molecules that can coordinate selectively with the CSP. The dependence of chiral recognition on the formation of the diastereomeric complex imposes constraints on the proximity of the metal binding sites, usually either a hydroxy or an amine $a$ to a carboxylic acid in the analyte. In addition, the copper-salt containing mobile phase absorbs in the UV region, decreasing detection sensitivity. It is interesting to note that the only commercially successful CSP for TLC is based on the ligand-exchange technique.

5 PROTEIN-BASED CHIRAL STATIONARY PHASES

Protein-based CSPs comprise a diverse and important class of CSPs for chiral separations. Within this class of CSP, there are a number of commercially available columns including $a_1$-acid glycoprotein ($a_1$-AGP), bovine serum albumin (BSA), human serum albumin, ovomucoid, and cellobiohydrolase. Protein CSPs are natural binders of small molecules and have numerous sites due to a variety of aromatic, basic, and acidic amino acids available to interact with the chiral analyte. These CSPs can be used in the reversed-phase mode and there are a limited number of variables to control in developing a separation method. Although the bonded-protein CSPs can be used to separate a wide variety of compounds, the applicability of each type of CSP is generally limited to a class of compounds and their related structures. For example, cellobiohydrolase CSP columns can most readily resolve primary amines and some secondary amines and amides whereas ovomucoid CSP is commonly employed in the separation of cyclic and secondary amines containing an aromatic group. The earlier versions of the protein-based CSP columns suffered from a lack of hardness and longevity. They also tend to be more labile. The second generation of these columns showed improvements in stability and efficiency. Advantages of protein-based CSPs include low column capacity, limited solvent options and the inability to reverse the elution order of the analyte. The two most commonly employed protein CSPs are BSA and $a_1$-AGP. A summary of commercially available protein-based CSPs are listed in Table 2.

5.1 Bovine Serum Albumin Chiral Stationary Phase

5.1.1 Properties and Structure

BSA is a globular protein having a molecular weight of 66210. The protein consists of 581 single chain amino acids, and 17 intrachain disulphide bridges, which connect the 34 half-cystines with the formation of 9 double loops. BSA is a relatively acidic protein with an isoelectric point of 4.7. It is highly soluble in water but, like most globular proteins, it precipitates from solution at high salt concentrations. At pH 7.0 it has a net charge of $\sim18$. It exhibits hydrophobic character, and numerous examples of bindings of organic compounds to albumins have been reported. Hydrophobic interaction has been shown to represent an important contribution to the total affinity of organic ligand to BSA. However, other

interactions such as electrostatic interactions, hydrogen bonding, and charge-transfer contribute to the total affinity as well.

The first observation of the enantioselective properties of an albumin was made in 1958 by McMenamy and Oncley, who demonstrated that the affinity for L-tryptophan exceeded that of D-tryptophan by a factor of 100 in a radioisotope labeling experiment and using a dialysis technique. This finding was later confirmed in 1973 by Stewart and Doherty when they demonstrated in an affinity chromatography on BSA immobilized to Sepharose that the D-enantiomer eluted under the conditions where L-enantiomer was retained. Since then there have been extensive investigations of the chromatographic behavior of various racemic compounds under different mobile phase conditions. The BSA-silica columns for HPLC were introduced commercially in 1983.

5.2.2 Applications

The mobile phases generally used in BSA columns are aqueous buffers with a limited pH range, mixed with organic modifiers such as 1-propanol. Retention and enantioselectivity properties on the BSA columns can be changed by varying parameters such as pH, ionic strength of the mobile phase, and temperature. Various N-acylamino acids, amines, aromatic amino acids, sulfoxides and sulfoximine derivatives and related compounds, coumarin derivatives, and benzodiazepine derivatives have been shown to enantioresolve on BSA columns. The binding properties of BSA are highly dependent on the aqueous buffer system employed. This is partly due to the protein itself, that is, the overall charge and the conformation. Consequently, it is possible to optimize enantioresolution by a proper selection of mobile phase parameters.

5.2 α1-Acid Glycoprotein Chiral Stationary Phase

5.2.1 Properties and Structure

Human α1-AGP has a molecular weight of approximately 41 000. It is a single 181-amino acid peptide chain with five carbohydrate units, containing sialic acid, hexosamine, and neutral hexoses. The peptide chain comprises 55% of the molecular weight. α1-AGP contains two cystine disulfide cross-linkages, which connect residues 5 and 147 and residues 72 and 164. In phosphate buffer, the glycoprotein has an isoelectric point of 2.7. Stability studies indicate that α1-AGP column is very stable. It can be used at elevated temperatures (25–80°C), and can tolerate organic solvents such as pure 2-propanol. The columns also may be used over a wide pH range without denaturation. Storage of the columns can be done in a water–2-propanol mixture for 12 months with approximately 10% reduction in column retention characteristics.

α1-AGP column can be prepared by immobilization of the human plasma AGP on silica particles. The preparation is based on bonding the protein to diethylaminoethyl silica followed by a cross-linking procedure. The resulting enamines from the cross-linking process are reduced to secondary amines with cyanoborohydride. The α1-AGP column is commercially available under the trade name EnantioPac (LKB Products, Bromma, Sweden). Many of the advantages of the EnantioPac columns are associated with the reversed-phase mode of the column, which allows for direct injections as well as better regulation of retention and selectivity. Additionally, many basic and acidic drug substances without derivatization can be enantioresolved using the EnantioPac column. A second generation AGP column such as Chiral-AGP, on the other hand, uses covalent linkages to attach the protein to the silica support. Chiral-AGP columns are thus more stable and resistant to hydrolytic attack. Chiral-AGP columns contain 5 µm silica particles instead of 10 µm as in EnantioPac, which gives Chiral-AGP columns a smaller pore volume and greater surface area, adding to their mechanical stability. Bonding capacity of the chiral phase as well as loading capacity of the solute are directly dependent on the amount of protein bound to the silica particles, which in turn depends on the bonding technique and the surface area of the silica support.

5.2.2 Applications

α1-AGP CSP columns have wide application for the direct separation of many classes of pharmaceutical compounds, as well as amines, acids, and nonproteinolytic compounds. They are often used in the determination of enantiomers at low concentrations in biological fluids such as plasma and urine. Concentration as low as 2 nmol L⁻¹ plasma has been detected using a Chiral-AGP column and fluorescence detection. Enantioresolved acidic drugs on AGP columns include ibuprofen, ketoprofen, and naproxen. Basic drugs such as disopyramide, tropicamide, atropine, and homatropine have also been resolved on AGP columns. In addition, AGP columns have been shown to baseline-resolve various other compounds including alpenolol, atenolol, ephedrine, and warfarin.

Concentration and properties of modifiers in the aqueous mobile phase play an important role in retention and selectivity of the solutes on AGP CSPs. Retention and enantioselectivity are found to decrease with increasing concentration of uncharged organic modifiers such as methanol, ethanol, 2-propanol, and acetonitrile. This trend is not universal, however. For example, in the cases of mephenytoin and methylphenobarbital, chiral...
resolution can be improved by adding uncharged modifier such as 2-propanol to the mobile phase. Enantioresolution of tertiary amines such as mepivacaine and bupivacaine, on the other hand, are not affected by the addition of organic modifier. Adding up to 8% propanol to the mobile phase results in no change in chiral resolution although the retention of these solutes decreases significantly under these conditions.\(^\text{(26)}\)

Solute retention is generally found to increase when a modifier with the opposite charge is added to the solutes. Additions of same charge modifiers to the solutes tend to decrease retention time. The enantiomers of propiomazine, a fentiazin derivative, which could not be resolved on an \(\alpha_1\)-AGP column when using phosphate buffer at pH 7.55 as a mobile phase, was baseline resolved with a longer retention time upon adding 1 mM \(N,N\)-dimethyloctylamine (DMOA) to the mobile phase.\(^\text{(34)}\) The changes observed in the selectivity are believed to result from the changes in \(\alpha_1\)-AGP conformations, which in turn result from pH changes in the mobile phase. Changes in pH have been found to affect retention and selectivity for basic, acidic, and nonprotolytic compounds. While the separation of the weakly acidic hexobarbital and basic metoprolol increases with increasing mobile phase pH, enantioselectivity of 2-phenoxypropionic acid (\(pK_a\) 4.6) decreases at higher pHs.\(^\text{(31)}\) Retention and enantioselectivity are also influenced by column temperature. Generally, retention, resolution, and separation factors decrease with increasing temperature. Separation efficiency, on the other hand, usually increases at higher temperatures.

5.2.3 Separation Mechanism

Although a great deal is known about the scientific basis of separation, that is, differences in binding between proteins and drug enantiomers, the mechanisms for enantioreognition are not well understood. It is known that the native conformation of a protein can be changed by varying pH and adding organic modifier. The \(\alpha_1\)-AGP molecule is believed to remain flexible in the column even after bonding with silica support. Hence, the addition of modifiers to the mobile phase is thought to affect the AGP molecule, inducing different binding properties.\(^\text{(26, 31)}\)

6 CARBOHYDRATE-BASED PHASES

Cellulose and amylose are among the most common natural polymers of this class of CSP. They are abundant in nature. In their native state, cellulose and amylose are poor chiral selectors. Improved chromatography and enantioselectivity of these chiral selectors can be achieved by derivatizing their hydroxyl groups with aromatic moieties through ester or carbamate linkages to decrease bulk polarity and provide additional interaction between the CSP and the solute.\(^\text{(35)}\) The initial work on functionalized cellulose-based CSP was investigated in Europe, but it was Daicel, Ltd. (Tokyo, Japan) who commercialized a series of cellulose and amylose CSP.\(^\text{(16)}\) A number of these commercialized stationary phases are shown in (7–16). Structures (7–10) are derivatives of cellulose carbamate CSPs. Structures (11–14) are derivatives of cellulose ester CSPs. Structures (15) and (16) are coated CSPs consisting of derivatives of amylose. The 3,5-dimethylphenyl derivatives are the most widely used cellulose-based CSP (ChiraCel OD, Daicel) and amylose-based CSP (ChiraCel AD, Daicel), respectively.\(^\text{(16)}\) Presently, there are nine cellulose derivative-based columns and two amylose-derivative CSPs produced by Daicel, Ltd. These CSPs are generally used in the normal phase mode, with the exception of two types which are conditioned for the reversed-phase mode. The molecular weight of a cellulose derivative affects chiral recognition and column efficiency. Cellulose and amylose columns have good capacity in the normal phase mode and are often used in the preparative-scale separations.\(^\text{(35)}\)

Derivatized cellulose and amylose are immobilized on a silica support. Mobile phases commonly employed are hexane: 2-propanol mixtures at various concentrations and occasionally more polar alcohols, such as methanol or ethanol, as well as aqueous-alcohol mixtures. These phases may not be used with solvents of intermediate polarity, for example, methylene chloride, acetone, tetrahydrofuran, and acetonitrile (over 1%). The main disadvantages of these phases are the limitations in
pressure and solvent used because these phases are not covalently bonded but merely adsorbed on the silica.

### 6.1 Cellulose- and Amylose-based Chiral Stationary Phases

#### 6.1.1 Properties and Structures

Cellulose and amylose are naturally occurring polymers. They have highly organized structures, consisting of hydrogen-bonded chains of 1,4-linked D-(+)-glucose units. The glucose units on amylose are the same as the cyclodextrins and are connected via 1,4-β-linkages. However, the linkages in cellulose are 1,4-α-linkages. Cellulosic and amylosic phases have been used extensively for chiral separations. The most frequently used cellulose phase, in pure polymer form, is cellulose triacetate, which is commercially known as microcrystalline cellulose triacetate (MCA) (Daicel Chemical Industries, Ltd., Tokyo, Japan). Various cellulose ester derivatives on a silica gel support as HPLC columns are also commercially available (Daicel Chemical Industries, Ltd.). These columns appear to have good stability; however, because these chiral polymers are not attached covalently to the silica support, but are coated on silanized wide pore silica particles, caution must be taken in selecting mobile phase solvents. Mobile phases such as hexane–2-propanol or alcohols can be used in these columns. The columns should be stored in hexane at low temperature (~4°C).

#### 6.1.2 Applications

Cellulosic and amylosic phases have been successful in resolving structurally diverse compounds. MCA columns can be used to enantioresolve polar compounds such as amines, amides, imides, esters, and ketones. Chiral selectivity seems to improve with a phenyl or a cycloalkyl group near the stereogenic center. Other phases based upon the DNB moiety are also commercially available.

#### 6.1.3 Separation Mechanism

The chiral recognition sites on these carbohydrate-based CSPs are thought to be channels or grooves in the polymer matrix. The analytes are probably included in these grooves. This is evident by the enhanced enantiorecognition observed for many solutes when the steric bulk of the alcohol modifier is added to the mobile phase. Chiral recognition appears to require the presence of an aromatic ring, for π–π interactions, as well as polar sites of unsaturation and hydrogen bonding functionalities. Although the mechanism of separation by cellulose esters and carbamates is unclear, it is believed that chiral interactions result from the ester and urethane linkages.

### 7 Pirkle Chiral Stationary Phases

The first commercially available and successful CSP was invented by William Pirkle, an organic chemist with experience in chiral synthesis. The first generation of the “Pirkle phases”, named after its creator, was introduced for LC in 1979. The first generation Pirkle phase was based on the N-3,5-dinitrobenzoyl (DNB) moiety, which was immobilized on a silica support. Pirkle then introduced the concept that if a particular chiral selector is able to resolve certain analytes, it is more likely that a similar chiral selector to the original chiral selector could also be used to separate the analytes. Following this notion, a second generation of Pirkle phases, which were based on N-(2-naphthyl)-α-amino acids, was made. Since these CSPs are produced synthetically, the stationary phase is often available in either absolute configuration.

#### 7.1 Properties, Structures, and Applications

Using the above concept, Pirkle developed two commercially successful CSPs which are shown in (17) and (18). These phases consisted of N-(3,5-DNB) phenylglycine or covalently linked to an aminopropyl silica. These first Pirkle phases were very successful at enantioresolving compounds containing naphthyl moieties near the stereogenic center. Other phases based upon the DNB moiety were later developed (19–21). These included derivatives of leucine, ionically and covalently linked to an aminopropyl silica support. Since the DNB moiety is a π-acceptor, analytes for these CSPs should possess a π-donor group such as an aromatic ring with an alkyl, ether or amino substituent. These DNB phases have been successful at resolving a large number of compounds such as π-donor-substituted amines, alcohols, amino alcohols, and sulfides. While the covalently bonded version of these columns can be used with relatively polar mobile phases, the enantioselectivity and stability are much greater when using normal phase solvents. A second generation of Pirkle phases, which were based on N-(2-naphthyl)-α-amino acids were synthesized, providing reciprocity to the first DNB phases.
N-(2-naphthyl)-α-amino acids phases are π-donors, therefore analytes for these CSPs should possess a π-acceptor group. These columns showed selectivity toward analytes containing a 3,5-DNB group, such as 3,5-dinitrophenyl carbamates, ureas of chiral alcohols, and amines.

The most recent addition to the Pirkle phases is the commercial column marketed as the Whelk-O-1 phase (see 22). The phase contains a chiral selector with a wedge-like chiral surface, with one edge containing a 3,5-DNB π-acidic moiety and the other edge comprising the π-basic tetrahydrophenanthrene ring system. The two edges are linked together by the amide linkages. The presence of both the π-acid and π-basic, as well as the amide linkages, offers rigidity, and greater versatility than any other Pirkle phases. The Whelk-O-1 phase contains dipole stacking and hydrogen-bonding interaction sites, and imposes fewer structural constraints of the solutes and the mobile phase conditions. Because this chiral selector is small, it also promotes high bonded ligand densities in the stationary phase. This feature, coupled with the high enantioselectivity achieved with the phase, allows the Whelk-O-1 phase to be used in the preparative-scale separations. Additionally, the chiral selector can interact with either the (R–R) or the (S–S) configuration of the solutes, giving the possibility of changing the elution order. This CSP has been shown to enantioresolve naproxen, warfarin, and its p-chloro analog, under the reversed-phase mode and nonaqueous reversed-phase condition.

The mobile phases typically used with the Pirkle phases are the nonpolar organic mobile phases such as hexane, with 2-propanol or ethanol as organic modifiers. Under these conditions, retention of the solutes decreases as the mobile phase polarity increases, following the normal phase mode behavior. Since the mobile phase only weakly interacts with the CSP, and can be easily displaced by the solutes, specific enantiomeric interactions are promoted. The Pirkle phases are commonly used in the normal phase mode, although some have been used in the reversed-phase mode.

### 7.2 Separation Mechanism

Of all the commercially available CSPs for HPLC, the chiral recognition mechanism for the Pirkle phases is perhaps the best understood. Enantiorecognition on the Pirkle phases is believed to depend on complementary interactions between the chiral selector and the solutes. The interactions involved are thought to include dipole–dipole interactions, π–π, hydrogen bonding, and steric hindrance as shown in Figure 2. These interactions contribute to the overall stability of the diastereomeric complexes formed between the individual enantiomer and the chiral selector on the stationary phase. The π–π interaction arises through the association of aromatic systems with complementary electron-withdrawing and electron-donating substituents...
such as the nitro and alkyl groups, respectively. The aromatic system deficient in electrons is referred to as \( \pi \)-acid, in contrast to the electron-rich system, which is called \( \pi \)-base. In order to promote and enhance chiral recognition, functional groups are often introduced into the solute through achiral derivatization. The amines may be derivatized with 3,5-DNB chloride to create a \( \pi \)-acid aromatic group to the solute, thereby enhancing a diastereomeric complexation with a \( \pi \)-basic, \((R)\)-N-(2-naphthyl)-alanine, chiral selector in the stationary phase.\(^{(44)}\) Also, derivatizing the solute may have an additional advantage of increasing solute solubility.

It appears that three unique interactions from the stereogenic centers of the solutes and the chiral ligand in the stationary phase are necessary for enantiorecognition. This model describing three unique interactions is called the “3-point interaction model”. It was first proposed by Dalgleish.\(^{(48)}\) Pirkle had recently restated the “3-point rule” as “chiral recognition requires a minimum of three simultaneous interactions between the CSP and at least one of the enantiomers, with at least one of the interactions being stereochemically dependent”.\(^{(49)}\) While no simple model can explain all the observations of chiral recognition, the three-point attachment model has greatly aided our understanding of the chiral recognition process.

8 CYCLODEXTRIN CHIRAL STATIONARY PHASES

Another general strategy to obtain optical resolutions employs the inclusion of the analyte into a chiral cavity. This strategy was first introduced by Dotsevi et al.\(^{(50)}\) who used a crown ether bound to silica gel. Although the chiral crown ether phases were commercialized, for example, Diacel Crown-Pak, the majority of inclusion-based separations utilized bound cyclodextrin CSPs. Cyclodextrin CSPs immobilize the cyclodextrins to a solid support in such a way that the cyclodextrins are free to interact with solutes in solution. One of the earlier uses of cyclodextrins was as mobile phase modifiers in TLC.\(^{(51,52)}\) Immobilizing cyclodextrin on a solid support yields several advantages over its use as a mobile phase modifier. For example, the solubility of \( \beta \)-cyclodextrin in the mobile phase is fairly low, and the efficiency obtained is often poor. Polymerized cyclodextrin gels were initially used as stationary phases in column chromatography but with limited success.\(^{(53,54)}\)

The use of cyclodextrins in HPLC was introduced when Fujimura et al.\(^{(55)}\) and Kawaguchi et al.\(^{(56)}\) developed a method to attach different cyclodextrins to silica gel via ethylene diamine linkages. Unfortunately, these phases were hydrolytically unstable and unsuitable for commercialization. A new cyclodextrin packing, which contained no nitrogen linkages, was later introduced by Armstrong.\(^{(57)}\) The new columns were thought to be more widely useful and commercially feasible. The nitrogen linkages were replaced by a 6–10 atom spacer. The linkages and the cyclodextrins were hydrolytically stable, and the stationary phases had increased loading and efficiency. This stable cyclodextrin-bonded phase is sold commercially under the trade name Cyclobond (Advanced Separation Technologies, Whippany, New Jersey). This stationary phase was the first chiral CSP to be developed for use in the reversed-phase mode and has been shown to successfully resolve diverse isomers formerly thought to be difficult to separate.\(^{(58–60)}\)

8.1 Properties and Structures

Cyclodextrins are cyclic oligosaccharides naturally formed by the action of Bacillus macerans on starch.\(^{(61,62)}\) They can also be produced by use of the enzyme cyclodextrin transglycosylase from starch.\(^{(63)}\) There have been several procedures used to control the ratios of cyclodextrins produced. One is the addition of a substance to the reaction mixture to favor one form of cyclodextrin over another. For instance, the addition of 1-decanol and 1-nonanol favorably induces the formation of \( \alpha \)-cyclodextrin.\(^{(64)}\) In the presence of hexane or toluene, on the other hand, \( \beta \)-cyclodextrin is more strongly promoted. Both \( \alpha \)- and \( \beta \)-cyclodextrins are simultaneously produced in the presence of 1-heptanol.\(^{(61,64)}\) The native cyclodextrins contain 6 to 12 glucose units, which are connected to each other by \( \alpha \)-(1,4) linkages. There are three commercially available cyclodextrin homologs: \( \alpha \)-cyclodextrin (cyclodextrinomyllose), \( \beta \)-cyclodextrin (cyclodextrinomylose), and \( \gamma \)-cyclodextrin (cyclooctamyllose) as shown in (23–25), respectively. The larger cyclodextrin homologs must be individually produced and isolated.

The Greek letter preceding the name of the cyclodextrin designates the number of glucose subunits: \( \alpha = 6 \), \( \beta = 7 \), and \( \gamma = 8 \). Each glucose unit on the cyclodextrin is chiral. Cyclodextrins are toroidal in shape with
a relatively hydrophobic internal cavity. The 2-hydroxyl groups at the rim of the cyclodextrin cavity project in a clockwise direction. The cyclodextrin exterior is relatively hydrophilic due to the presence of the primary and secondary hydroxyl groups. The primary hydroxyl group on C-6 is free to rotate and can partially block the cyclodextrin cavity at the narrow end. The ability of cyclodextrins to form inclusion complexes with a variety of guest molecules and ions makes the cyclodextrins particularly useful for chiral separations (Figure 3).  

The cyclodextrins have a number of chemical and physical properties in common. Among these properties are:

- cyclodextrins are nonreducing; glucose is the only product of acid hydrolysis; molecular weights are always integral numbers of 162.1, the value for glucose;
- cyclodextrins are nontoxic; cyclodextrins do not appreciably absorb UV or visible light. The cyclodextrin molecules as a whole are hydrophilic making these CSPs completely compatible with aqueous mobile phases. Since cyclodextrin CSPs are compatible with aqueous mobile phases, method development is aided by the use of buffers and organic modifiers in adjusting column selectivity.

### 8.2 Applications

The most commonly used cyclodextrin in HPLC has been the native β-cyclodextrin (24). A variety of water soluble–insoluble compounds can fit into the hydrophobic cavity, forming reversible host–guest inclusion complexes. It is well known that molecules possessing an aromatic group such as naphthyl or biphenyl in close proximity to the stereogenic center are particularly amenable for separation. The β-cyclodextrin column has shown excellent selectivity for amino acid derivatives. For example, the native β-cyclodextrin phase has been used to resolve a variety of racemates including dansylamino acids, β-naphthyl ester derivatives of amino acids, and β-naphthylamide. It is thought that underivatized amino acids are perhaps too small to bind tightly to the cyclodextrin cavity, and subsequently cannot be enantioresolved. When a dansyl group is incorporated in the amino acid, however, strong inclusion complexes between the cyclodextrin and the derivatized amino acid can be formed, and baseline resolution is achieved. Either the carboxyl group or the amino group on the amino acid can be derivatized. Derivatization of both groups appears to result in reduced chiral recognition. Enantiomeric derivatives of ferrocene, ruthenocene, and osmocene, as well as several racemic and diastereomeric 2,2-binaphthylidyl crown ethers, have also been successfully resolved on the β-cyclodextrin phase. It should be noted that although the crown ethers do not contain a chiral carbon, they still exist as enantiomers because of the staggered position of adjacent naphthyl rings.
α-Cyclodextrin is suitable for separating small molecules such as tryptophan, phenylalanine, tyrosine, and their analogs. γ-Cyclodextrin has been used for the separation of di- and tripeptides.

Cyclodextrin-bonded phases provide a rapid and specific technique for the pharmacological evaluation of racemic drugs. Chiral drugs such as ketoprofen, mephenytoin, chlorpheniramine, and the barbiturates mephobarbital and hexobarbital, have been separated by the cyclodextrin column. Many diastereomers, geometric isomers, and epimers, can be resolved using cyclodextrin phases as well. For example, cis- and trans-benzo[a]pyrene were completely separated on a γ-cyclodextrin column. In addition, cyclodextrin phases are of great utility in enantioresolving structural isomers, such as the ortho-, meta-, and para-isomers of nitroaniline, xylene, cresols, nitrophenols, and substituted benzoic acids. An extremely sensitive test of optical purity can be achieved with the cyclodextrin columns. Detection of as little as 0.2% of one enantiomer in a racemic mixture has been shown to be feasible using the cyclodextrin column.

Limitations with the selectivity of the native cyclodextrins led to the development of various functionalized cyclodextrin-based stationary phases. These derivatized cyclodextrin phases include acetylated, sulfated, 2-hydroxypropyl, 3,5-dimethylphenylcarbamoylated, and 1-naphthylethylcarbamoylated cyclodextrin. Since each of the glucose molecules on a cyclodextrin provides three hydroxyl groups to which a substituent may be attached, there are multiple sites on the cyclodextrin available for derivatization. Typically, each β-cyclodextrin, which contains 21 hydroxyl groups, has a degree of substitution ranging from 3 to 10 derivatized groups per cyclodextrin molecule. The groups on these functionalized cyclodextrins enhance chiral recognition by a variety of means. In some cases, the groups mainly serve to extend the chiral cyclodextrin cavity and in others they may provide alternate interaction sites. For example, in the case of the naphthylethylcarbamoylated cyclodextrin the naphthyl ring provides a π-basic site while the carbamate linkage provides additional hydrogen bonding and dipolar interaction sites. The sulfate group on the sulfated cyclodextrin provides the potential for ion-pair formation while the two hydroxypropyl substituents add additional stereogenic centers to the cyclodextrin. One feature that is particularly advantageous with these functionalized cyclodextrins is that they often exhibit enantioselectivity in the hydroorganic reversed-phase as well as normal phase, and polar organic mobile phase conditions. This is unusual in that each mode can provide chiral separations for compounds, which are not resolved under any other types of mobile phase conditions.

Most chiral separations reported to date using the cyclodextrin columns have been accomplished in the reversed-phase mode using aqueous buffers with a small amount of organic modifiers. However, polar organic mobile phases have gained in popularity recently because of their ease of sample removal and reduced rate of column degradation. In these cases, the solutes are thought to occupy the top of the cyclodextrin cavity like a “lid”, rather than fit in the cavity because of the more nonpolar mobile phase. The commonly used mobile phases in the normal phase mode of separations are hexane–isopropanol. Separation in the normal phase mode is thought to be analogous to those of diol columns.

### 8.3 Separation Mechanism

The separation mechanism thought to be responsible for the chiral recognition observed with the cyclodextrin-bonded phases is based upon the formation of inclusion complex between the hydrophobic moiety of the solute and the hydrophobic cavity of the cyclodextrin. This has been demonstrated by performing a separation in a normal phase mode using hexane–isopropanol mobile phase on a β-cyclodextrin column, a system by which the solute is excluded from the cyclodextrin cavity because of a more hydrophilic mobile phase occupies the cavity. The inclusion complex formed between the solute and cyclodextrin cavity should also be a tight fit. This is apparent by the fact that better enantioresolution using a β-cyclodextrin column is obtained when the solute is about the size of biphenyl or naphthalene than when smaller or larger size solutes are used. It is possible that smaller compounds may not be rigidly held in the cavity, resulting in a less stable diastereomeric complex and subsequently less successful separation. Moreover, the stereogenic center of the solute or the substituent attached to the stereogenic center of the solute should be able to interact with the rim of the cyclodextrin cavity in order to create strong interactions necessary for chiral separations.

The restricted conformational freedom of the 2- and 3-hydroxyl groups at the cyclodextrin rim is thought to play an important role for the chiral recognition properties in the cyclodextrins. This is evident by the modeling studies using (R)- and (S)-propanolol with β-cyclodextrin. The (R)- and (S)-propanolol were placed inside the cyclodextrin cavity in an identical manner, and with the 3-hydroxyl group of the cyclodextrin lined up for an ideal hydrogen bonding with the hydroxyl groups on (R)- and (S)-propanolol as shown in Figure 4. An important difference which exists between the two complexes formed is at the secondary amine group. In the (R)-complex, the bond distances between the nitrogen on the amine group of the solute and the 2-
and 3-hydroxyl groups on the cyclodextrin are 0.33 and 0.28 nm, respectively. In contrast, the (S)-complex has the respective bond distances of 0.38 and 0.45 nm. The model suggests that (R)-propranolol is positioned more favorably for hydrogen bonding with the cyclodextrin, and can preferentially interact with the chiral selector in a way that the (S)-isomer cannot. This difference in their interaction results in enantioresognition.

9 THE MACROCYCLIC ANTIBIOTIC CHIRAL STATIONARY PHASES

The macrocyclic antibiotics and their derivatives have formed one of the newest and perhaps more versatile class of chiral selectors in HPLC. They are excellent chiral selectors, and can be bonded to silica gel via linkage chains using a variety of chemistries. They can be used in either the reversed-phase or the normal phase mode. Enantioselectivities in each mode have been shown to be different. Furthermore, the macrocyclic antibiotics can be derivatized to alter their selectivity. The bonded macrocyclic antibiotic CSPs resemble the protein-based CSPs in many ways. However, the macrocyclic antibiotic CSPs are more stable and have greater capacities than the protein-based CSPs. There are literally hundreds of macrocyclic antibiotics that have yet to be investigated. Their versatility in enantioresolving chiral analytes is becoming well known. Thus far, the two most successful structural types of antibiotics used for separations are *ansa* compounds and glycopeptides. These two classes of macrocyclic antibiotics will be the focus of our discussion.

9.1 Properties and Structures

The ansamycins include *ansa* compounds such as rifamycin B, rifamycin SV, rifamide, and rifampim. They are isolated from the fermentation broth of the bacteria *Nocardia mediterranei*. These compounds contain a characteristic *ansa* structure, a ring structure or chromophore that is spanned by an aliphatic chain. As shown in Figure 5, the rifamycins differ from each other only in the type and the location of the substituents on their naphthoquinone ring. Of the rifamycins, rifamycin B is one of the more common members and has been utilized as a CSP for HPLC. Rifamycin B has nine stereogenic centers, four hydroxyl groups, one carboxylic acid moiety, and one amide bond. Rifamycin B has a molecular weight of 756 and is more soluble in ethanol and methanol.

than in water. The substituent on rifamycin B is an oxyacetic acid (–OCH2COOH), thus the carboxylic and the hydroxyl groups on rifamycin B are ionizable and rifamycin B can exist as a dibasic acid.

The glycopeptide macrocyclic antibiotics vancomycin, thio- strepton, and teicoplanin are produced by Streptomyces orientalis, Streptomyces azureus, and Actinoplanes teichomyceticus, respectively. The glycopeptide macrocyclic antibiotics are soluble in water, buffers, and acidic aqueous solutions, and are less soluble at neutral pH. They are moderately soluble in polar aprotic solvents, such as dimethyl sulfoxide (DMSO) and dimethyl formamide (DMF), but are insoluble in most nonpolar organic solvents. The three glycopeptide macrocyclic antibiotics have many structural features and physico-chemical properties in common. Table 3 shows a comparison of the macrocyclic antibiotics.

Among the three glycopeptide macrocyclic antibiotics discussed, vancomycin (26) is the smallest in size (molecular weight 1449, 18 stereogenic centers) while thio- strepton (27) is of intermediate size (molecular weight 1665, 17 stereogenic centers), and teicoplanin (28) is the largest in size (molecular weight 1877, 23 stereogenic centers). The macrocycles contain both ether and peptide linkages. The aglycon portion of vancomycin and teicoplanin consists of two chloro-substituted aromatic rings. In thio- strepton the analogous portion lacks a chloro-substituent. There is a carboxylic moiety on the aglycon of both vancomycin and teicoplanin. Thio- strepton contains in its aglycon portion five thiazole rings and one quinoline ring. The type and number of pendant carbohydrate moieties vary among the glycopeptide macrocyclic antibiotics as well. Vancomycin contains D-glucose and vancosamine. Teicoplanin, on the other hand, has three attached monosaccharides, two D-glucosamines and one D-mannose. Thio- strepton has no attached carbohydrate moieties.

In addition to the fused macrocyclic rings and the attached pendant carbohydrate moieties, the glycopeptide macrocyclic antibiotics have various analogous ionizable groups, which are thought to control their charge and enantioselective properties. For example, vancomycin and thio- strepton have a secondary amine unlike teicoplanin, which contains only a primary amine group.
9.2 Applications

Currently, there are two types of glycopeptide-based CSPs available commercially: vancomycin and teicoplanin. The macrocyclic antibiotics can be attached to silica gel via epoxy-terminated organosilane, as has been used with the cyclodextrins, or by reacting the macrocyclic antibiotics with an isocyanate-terminated organosilane in anhydrous DMF. The macrocyclic antibiotics are multimodal CSPs. These CSPs can be useful in preparative-scale separations. They can be used effectively in the reversed-phase, normal phase, and polar organic modes. Different compounds are resolved in each mode. When changing from one mode to another, there does not appear to be any deleterious effects to the stationary phases or any irreversible changes in the enantioselectivity. The macrocyclic antibiotics have been shown to exhibit excellent enantioselectivity for native amino acids, peptides, \( \alpha \)-hydroxycarboxylic acids, and a variety of neutral analytes including cyclic amides and amines. Neutral molecules, for example, devrinol and 5-methyl-5-phenylhydantoin, seem to show considerable enantioselective retention on the macrocyclic antibiotic CSPs. The chiral selectors appear to be stable and the integrity of the CSP is excellent in all separation modes. For example, compounds resolved in reversed-phase mode using vancomycin-bonded phase column include bromacil, devrinol and coumaral chlor enantiomers whereas in normal mode the same column showed enantioselectivity for 3-[2-(bromoacetamido)acetamido]-PROXYL and N-(3,5-DNB)-\( \alpha \)-methylbenzalamine. Of the available modes, the reversed-phase mode is probably more widely employed when using the macrocyclic antibiotics as a CSP.

In comparison to the other two CSPs most often used in the reversed-phase mode, which are the protein columns and the cyclodextrin-based columns, the macrocyclic antibiotic stationary phases have similarities and differences with both of these classes. Similar to the protein columns, the macrocyclic antibiotics contain ionizable groups, and consequently their charge and possibly conformation can vary with the pH of the mobile phase. The effect of mobile phase pH, however, is not observed when using the cyclodextrin CSPs because the cyclodextrins remain neutral at pH 3–8.5, which is the pH range commonly used in reversed-phase HPLC. Like the protein phases and the cyclodextrin phases, it is not necessary to derivatize racemic analytes before separation on the macrocyclic antibiotic CSPs. Most macrocyclic antibiotics contain peptide bonds, some have carbohydrate moieties, and a few, such as vancomycin, have both features.

Optimization of reversed-phase separations can be achieved in a similar way as for cyclodextrin-based columns. Retention can be changed by varying the amount of organic modifier, such as acetonitrile and methanol, and the mobile phase pH. For example, using teicoplanin CSP, with 100% triethylammonium acetate pH 7 buffer, 5-methyl-5-phenylhydantoin has a \( k > 4 \), where \( k \) is the capacity factor, but with acetonitrile–1% triethylammonium acetate pH 7 buffer (60:40 v/v), \( k \) is nearly zero or the analyte elutes near the dead volume of the column. A plot of retention vs mobile-phase composition shows the same U-shaped curve, which has been observed previously for chiral solutes on cyclodextrin-based columns and for proteins and peptides on reversed-phase columns. Typical normal phase retention behavior is found on a teicoplanin column. Retention and enantioselectivity are highest when the mobile phase consists mainly of the nonpolar component, such as hexane. Both retention and selectivity decrease as the amount of ethanol in the mobile phase is increased.

In addition, efficiency and selectivity can be affected by ionic strength, type of buffer, flow rate, and other additives. On a teicoplanin column under a normal phase mode, flow rate does not affect enantioselectivity or \( \alpha \), but does affect the separation efficiency. This is reflected by the inverse relationship between resolution \( (R_S) \) and flow rate. Decreasing the flow rate increases the resolution. However, decreasing the flow rate below 0.5 mL min\(^{-1}\) does not continue to produce an increase in resolution. It is believed that this is the result of poor stationary phase mass transfer. Temperature also has been shown to affect chiral separations using the macrocyclic antibiotic CSPs. Lowering the temperature appears to enhance enantioseparations by increasing \( \alpha \). Using the reversed-phase mode on a vancomycin CSP, the separation of \( N \)-carbamyl-D,L-phenylalanine increased \( \alpha \) of 1.00 and \( R_S \) of 0 to \( \alpha \) of 1.23 and \( R_S \) of 1.0 upon decreasing the temperature from 45°C to 15°C. Lowering the temperature in general enhances resolution and selectivity but concurrently causes an increase in retention time.

9.3 Separation Mechanism

It is thought that the size, shape, geometric arrangement, as well as the functional groups present in the macrocyclic antibiotics, help to determine their enantioselective properties. In addition to the charge interactions, the retention behavior of organic analytes in the reversed-phase mode indicates the importance of hydrophobic interactions between the analyte and the macrocyclic antibiotics. However, whether or not there is a true inclusion complex between the chiral selector and the analyte as in the case of the cyclodextrins or just an association of the analyte with the hydrophobic pocket is not known. Hydrogen bonding is believed to be essential for enantiorecognition, particularly in acetonitrile mobile phases.
10 FUTURE TRENDS

The development and success of the various CSPs have had a profound impact not only on the field of analytical separations but also the pharmaceutical industries, and other industries that manufactured or marketed chiral compounds. CSPs have been beneficial to the understanding of molecular recognition, chromatographic theory, and mechanism. In the future, chiral separations have the potential to aid in our understanding of the chemistry behind biological processes, diseases, and probing intermolecular interactions. Mechanistic studies of chiral compounds as well as CSPs will undoubtedly continue in the future.

1 INTRODUCTION

Chromatography is a general term applied to a wide variety of separation techniques based upon the sample partitioning between a moving phase, which can be a gas, liquid, or supercritical fluid and a stationary phase, which may be either a liquid or a solid. The discovery of chromatography is generally credited to Tswett who in 1906 described his work on using a chalk column to separate pigments in green leaves. The term “chromatography” was coined by Tswett to describe the colored zones that moved down the column. The technique languished for years with only periodic spurts of development following innovations such as partition and paper chromatography in the 1940s, gas chromatography (GC) and thin-layer chromatography in the 1950s, and various gel or size-exclusion methods in the early 1960s. Then in January, 1969, the Journal of Gas Chromatography officially changed its name and became the Journal of Chromatographic Science. This change reflected the renewed interest in the technique of liquid chromatography (LC) and officially signaled the beginning of the era of modern LC. This renewed interest in the oldest of chromatographic techniques was brought about both because of the successes and because of the failures of GC. On the one hand, GC provided a firm theoretical background upon which modern LC could build. However, this renewed interest in LC was being driven because of the inability of GC to handle thermally unstable or nonvolatile compounds. It has been estimated that fewer than 20% of organic compounds have sufficient volatility and thermal stability to successfully traverse a GC column. Admirers of LC also liked the selective interaction of its two chromatographic phases, and easy sample recovery because of its nondestructive detection methods and room temperature operation.

In the following years the technique was known by many acronyms. It was at various times designated high-pressure liquid chromatography, high-speed liquid chromatography, high-performance liquid chromatography (HPLC), high-priced liquid chromatography by cynical research directors, and finally modern liquid chromatography. The modifiers were all used to signify the difference in the technique brought about by small particle diameter stationary phases and the resulting high pressure needed to drive the mobile phase through the densely packed columns. These differences resulted in much faster separations with higher resolution than traditional column chromatography. Through the 1970s the technique grew with astounding speed, and for nine consecutive years from the middle of the 1970s to the early 1980s the technique led all other analytical instruments in growth rate in an annual survey conducted by the Industrial Research and Development magazine.

A discussion of the history of LC is beyond the scope of this volume; an excellent treatment has been published by Ettre. However, some perspective on the beginnings of modern LC is useful for an understanding of the technique as now practiced. The first comprehensive publication on the technique was a book edited by Kirkland, which grew from a short course offered by the Chromatography Forum of the Delaware Valley. This then laid the foundation for the definitive book, Introduction to Modern Liquid Chromatography.

During the development of modern LC, advances have been driven by both instrumentation and chemistry. The technique as now practiced produces elegant separations that have been developed through chemical manipulation of the stationary and mobile phases, which are then effected and detected by modern instrumentation.

2 FUNDAMENTALS OF CHROMATOGRAPHY

Chromatography is a separation method which employs two phases, one stationary and one mobile. As a mixture of analytes being carried through the system by the...
mobile phase (m) passes over and through the stationary phase (s), the individual components (X) of the mixture equilibrate or distribute between the two phases:

$$X_m \leftrightarrow X_s$$

The corresponding thermodynamic distribution coefficient $K$ is defined as the concentration of component (X) in the stationary phase divided by its concentration in the mobile phase, as shown in Equation (1).

$$K = \frac{[X]_s}{[X]_m}$$ (1)

The use of a typical equilibrium constant $K$ in chromatographic theory indicates that the system can be assumed to operate at equilibrium. As the analyte (X) proceeds through the system, it partitions between the two phases and not moving. If a solute is unretained and has no interaction with the stationary phase, it will elute at $t_0$, the hold-up time or dead time, which is the same time required for the mobile phase solvent molecules to traverse the column.

Another fundamental measure of retention is retention volume, $V_r$. It is sometimes preferable to record values of $V_r$ rather than $t_r$ since $t_r$ varies with the flow rate $F$, while $V_r$ is independent of $F$. If we wish to describe the volume of the mobile phase required to elute a retained compound, then the retention volume is the product of the retention time and the mobile phase flow rate, as shown in Equation (2).

$$V_r = t_rF$$ (2)

$V_0$ is a measure of the total volume of space available to the mobile phase in the system and correlates to $t_0$ as the volume necessary to elute an unretained compound. This is shown in Equation (3):

$$V_0 = t_0F$$ (3)

The most commonly used retention parameter in HPLC is the retention factor, $k'$. While the distribution coefficient, $K$, describes the concentration ratios, the retention factor, $k'$, as shown in Equation (4), is the ratio of the amount of solute in each phase.

$$k' = \frac{\text{moles of X in stationary phase}}{\text{moles of X in mobile phase}}$$

$$= \frac{[X]_sV_s}{[X]_mV_m} = \frac{K V_s}{V_m}$$ (4)

Equation (4) shows that $k'$ is directly proportional to $V_s$, and so $k'$ for each solute changes with the stationary phase loading on the silica support.

The retention factor is conveniently measured from retention parameters, as shown in Equation (5), since $k'$ also describes the amount of time the solute spends in each phase.

$$k' = \frac{t_r - t_0}{t_0} = \frac{V_r - V_0}{V_0}$$ (5)

Rearrangement of Equation (5) gives Equation (6):

$$V_r = V_0(1 + k')$$ (6)

The retention volume can then be related to the distribution coefficient by substituting Equation (4) for $k'$ in Equation (6), where $V_m = V_0$. This gives Equation (7):

$$V_r = V_0 + KV_s$$ (7)

2.2 Kinetic Considerations

It is obvious from Figure 1 that the chromatographic separation of components in a mixture is dependent on
two factors; the difference in retention times of two adjacent peaks, or more precisely the difference between peak maxima, and the peak widths. It was shown in the preceding discussion that the retention of a solute is a thermodynamic process controlled by the distribution coefficient and the stationary phase volume. The peak width, or band broadening, on the other hand is a function of the kinetics of the system.

Early papers on chromatographic theory described the technique in terms similar to distillation or extraction. The Nobel Prize winning work by Martin and Synge in 1941 introduced liquid–liquid (or partition) chromatography and the accompanying theory that became known as the *plate theory*. Although the plate theory was useful in the development of chromatography, it contained several poor assumptions. The theory assumed that equilibration between phases was instantaneous, and that longitudinal diffusion did not occur. Furthermore, it did not consider dimensions of phases or flow rates. An alternative to the plate theory which came into prominence in the 1950s was the so-called *’rate theory’*. The paper which has had the greatest impact was the one published by van Deemter et al. They described the chromatographic process in terms of kinetics and examined diffusion and mass transfer. The popular van Deemter plot resulted and the rate theory has become the backbone of chromatographic theory.

Several processes, which will be discussed shortly, contribute to the overall width of the band, and the contribution from each process can be described in terms of the variance ($\sigma^2$) of the chromatographic peak, which is the square of its standard deviation ($\sigma$).

The most common measure of efficiency of a chromatographic system is the plate number, $N$. Because the concept originated from the analogy with distillation, it was originally called the number of theoretical plates contained in a chromatographic column. This is not a useful analogy since a chromatographic column does not contain ‘plates’ but the terminology has become universally adopted and the original definition has persisted. The expression for the efficiency of a column is given by Equation (8).

$$N \equiv \left( \frac{t_r}{\sigma_t} \right)^2$$  \hspace{1cm} (8)

where $\sigma_t$ is the standard deviation in time units; the parameters $t_r$ and $\sigma_t$ must be measured in the same units so the number $N$ is dimensionless.

For Gaussian peaks we can express $\sigma$ in terms of peak width where the width of the peak at the baseline ($w_b$) is equal to $4\sigma$ (see Figure 2). $N$ is then given by Equation (9):

$$N \equiv \left( \frac{t_r}{\sigma_t} \right)^2 = 16 \left( \frac{t_r}{w_b} \right)^2$$  \hspace{1cm} (9)

Because measurements depending on $w_b$ rely on the accurate positioning of tangents to the chromatographic peak, another common calculation of $N$ uses the more easily measured peak width at half height, $w_{0.5}$, where $w_{0.5} = 2.354\sigma$, as shown in Equation (10):

$$N = \left( \frac{t_r}{\sigma_t} \right)^2 = 5.54 \left( \frac{t_r}{w_{0.5}} \right)^2$$  \hspace{1cm} (10)

The assumption for the measurement of peak widths in Equations (8–10) is that the peak is Gaussian. Unfortunately, few peaks are truly Gaussian and in general, for asymmetrical peaks, $N$, calculated by a Gaussian-based equation, increases the higher up on the peak the width is measured. Figure 3 shows the

![Figure 2 Evaluation of a chromatographic peak for the calculation of column efficiency.](image)

![Figure 3 Plot of percentage error in plate count determinations for asymmetrical peaks as a function of peak height at which the width is measured. The quantities B and A are illustrated in Figure 4. (Adapted from Foley and Dorsey.)](image)
error in plate count determinations for asymmetrical peaks as a function of the peak height at which the width is measured. A more accurate approach to efficiency measurement, shown in Equation (11), has been presented by Foley and Dorsey\(^7\) which takes into account the peak asymmetry.

\[
N = \frac{41.7(t_r/w_{0.1})^2}{1.25 + (B/A)} \tag{11}
\]

Here the peak width is measured at 10% of peak height and the asymmetric ratio or tailing factor is calculated as the ratio of \(B/A\) (see Figure 4). For a symmetrical peak, the \(B/A\) value will be 1, and the tailed peaks will have values greater than 1.

The plate number depends on the column length, making comparisons among columns difficult unless they are all of the same length. Another measure of efficiency which removes this dependency is given by the plate height, as shown in Equation (12):

\[
H = \frac{L}{N} \tag{12}
\]

where \(L\) is the length of the column. \(H\) can thus be thought of as the length of the column that contains one plate. For the highest efficiencies, the goal is to attain maximum \(N\) and small \(H\) values. We will see that \(H\) is proportional to the diameter of the stationary phase particles, so a better measure of expressing efficiency is the reduced plate height, \(h\), given by Equation (13):

\[
h = \frac{H}{d_p} \tag{13}
\]

where \(d_p\) is the stationary phase particle diameter. The reduced plate height is a dimensionless number (\(H\) and \(d_p\) being measured in the same units) and this calculation allows us to compare efficiencies of columns with different particle diameters. A well operated chromatographic system should have \(h\) values of 2 to 5.

As mentioned earlier, the extent of band broadening, and thus the efficiency of a chromatographic column, is dependent on several contributing processes. The four important band broadening phenomena to be considered are: (i) resistance to mass transfer (rmt); (ii) eddy diffusion (ed); (iii) longitudinal diffusion (long); and (iv) extra-column effects (ex). Each of these independently would produce a Gaussian band. The variances of each band broadening process are additive to give the overall variance of the system, as shown in Equation (14):

\[
\sigma_i^2 = \sigma_{rmt}^2 + \sigma_{ed}^2 + \sigma_{long}^2 + \sigma_{ex}^2 \tag{14}
\]

### 2.2.1 Resistance to Mass Transfer

As solute molecules interact with the column packing they continually transfer into and out of the stationary phase. Resistance to mass transfer relates to the rate at which the molecules exchange between phases and may be the dominant cause of band spreading.

If there were no flow through the column, there would be an equilibrium distribution of the analyte molecules between the mobile and stationary phases according to its partition coefficient. However, since there is flow, molecules in the mobile phase are swept downstream creating a condition of nonequilibrium in the immediately adjacent stationary phase. In order to restore the system to equilibrium, some molecules left behind in the stationary phase must desorb and enter the mobile phase, and some that were carried ahead must leave the mobile phase and sorb onto the stationary phase. This mass transfer takes a finite time and results in band broadening. The faster the mass transfer occurs, the less will be the effect. Both the stationary and mobile phase play a role in determining the rate of mass transfer. A discussion of all the contributing factors is given by Giddings,\(^8\) but three of the most important are the diffusion coefficient of the solute in the mobile phase \(D_m\), the stationary phase particle diameter \(d_p\), and mobile phase flow velocity \(v\). The relationship is shown by Equation (15):

\[
\text{rate of mass transfer} \propto \frac{d_p^2 v}{D_m} \tag{15}
\]

A molecule is in constant motion in solution. The larger the volume of mobile phase the molecule is in, the longer it will take to diffuse to a phase boundary. In chromatographic columns, the interstitial volume between particles is of the order of the same size as the particles themselves. Small particle diameter packings
therefore result in a much higher rate of contact and a greater rate of mass transfer. A high rate of diffusion of the solute in the mobile phase also increases the rate of contact by decreasing the time for the molecule to move between stationary phase particles. For this reason, many chromatographers choose low viscosity solvents as eluents and/or operate the system at elevated temperatures to increase the diffusion coefficient of the solute in the mobile phase.

The contribution to band broadening by flow velocity is obvious, since the faster the mobile phase is flowing, the farther molecules will be swept downstream before they exchange phases.

2.2.2 Eddy Diffusion

The velocity of the liquid moving through a column may vary significantly across the diameter of the column depending on the bed structure. The velocity of solutes being carried through the column by the mobile phase will therefore fluctuate between wide limits, and the total distance traveled by individual molecules will also vary. These variations are a result of different flow paths taken as a function of least resistance. Since the average velocity of the solute determines its retention time, these random fluctuations result in band broadening. There is still much disagreement about quantitation of this effect, but a generally accepted proportionality is given by Equation (16):

\[ \text{eddy diffusion} \propto d_p V^{1/3} \]  

The smaller the stationary phase particle diameter the closer will be the packing. This minimizes the variation in flow paths available to the molecules and reduces band broadening. High flow velocities affect the band broadening by causing molecules traveling though open pathways to move more rapidly than those in narrow pathways. The simple theory of eddy diffusion assumes that a particle will remain in a single flowpath. In practice, this is not the case since there is nothing to stop it from diffusing laterally from one flow path to another. This process, called “coupling”, averages out the two flowpaths and reduces the band broadening so that the final band width, although still greater than the initial band width, is less than if coupling had not occurred. So, rather than a direct relationship to flow velocity, as theory would predict, eddy diffusion is more nearly proportional to velocity to the 1/3 power.

2.2.3 Longitudinal Diffusion

As solute bands move through a column, diffusion of molecules into the surrounding solvent occurs from the region of higher concentration to the region of lower concentration in proportion to the diffusion coefficient, \( D_m \), according to Fick’s law. The faster the mobile phase moves, the less time the zone is in the column, the less time there is for diffusion, and the lower the band broadening due to diffusion. The relationship for longitudinal diffusion, \( D_{\text{long}} \), is given by Equation (17):

\[ D_{\text{long}} \propto \frac{D_m}{V} \]  

In principle, longitudinal diffusion may occur in both mobile and stationary phases, but because the rate is so small in the stationary phase, this factor can be neglected.

Combination of the three terms (resistance to mass transfer, eddy diffusion and longitudinal diffusion) gives the well known van Deemter expression shown in Equation (18):

\[ H = A + \frac{B}{V} + C V \]  

where the A term is due to eddy diffusion, the B term is due to longitudinal diffusion, and the C term is due to resistance to mass transfer. The familiar van Deemter plot is shown in Figure 5. This equation is also often written with reduced plate height and velocities, and is then known as the Knox equation.

2.2.4 Extra-column Effects

Band broadening can occur in other parts of the chromatographic system as well as in the column. Contributions to this extra-column broadening may come from the injector, the detector flow cell, and the connecting tubing. Slow time constants of detectors and recorders may also contribute. These extra-column effects are more severe for early, narrow peaks in the chromatogram than for later, broader peaks.

Figure 5 Van Deemter plot applied to LC.
2.3 Resolution

We have seen that the effective separation of two peaks is a function of both thermodynamic and kinetic effects. A common measure of the separation, the resolution, is the ratio of the distance between peak maxima and the average peak width.

\[
R_s = \frac{\text{peak separation}}{\text{average peak width}}
\]

(thermodynamic) (kinetic) (19)

In order to obtain peak separation, one of the components in a mixture must be more selectively retained than another, or we may say the column showed selectivity toward the components in the mixture. Selectivity is measured by the separation factor or relative retention (\(\alpha\)) and may be given by any of the relationships shown in Equation (20):

\[
\alpha_{2,1} = K_2 = \frac{k'_2}{k'_1} = \frac{t'_{r2}}{t'_{r1}} = \frac{t_{2} - t_m}{t_{1} - t_m}
\]

(20)

The relationship between the separation factor and the distribution coefficients \(K_2\) and \(K_1\) of the two components (2) and (1) emphasizes the thermodynamic basis of the separation.

Figure 6 illustrates the influence on resolution of peak separation and peak width. Figure 6(a) shows two components poorly resolved because of inadequate selectivity and large band widths. Figure 6(b) shows the components with the same band widths but good resolution as a result of improved selectivity. Figure 6(c) also demonstrates good resolution, but here narrow band widths are the contributing factor even though the selectivity is unchanged. The quantitative measure of resolution is given by Equation (21).

\[
R_s = \frac{2(t_{r2} - t_{r1})}{w_1 + w_2}
\]

(21)

In practice, it is seldom necessary to calculate the value of resolution. More frequently, the chromatographer simply looks at the shape of the peaks and estimates the \(R_s\) value from the peak shape. Of course, the concentrations and/or responses of the components in a mixture are rarely equal. Figure 7 illustrates the significance of the resolution value for two components with different relative concentrations.

The chromatographic control of resolution is a function of several factors. The fundamental resolution equation is shown in Equation (22):

\[
R_s = \left(\frac{N^{1/2}}{4}\right) \left(\frac{\alpha - 1}{\alpha}\right) \left(\frac{k'_{2}}{k'_{1}}\right)
\]

(22)

where \(\alpha = k'_{2}/k'_{1}\).

The plate number \(N\) (column factor) can be increased by lengthening the column, changing the packing particle diameter, or optimizing flow rate. However, improving resolution by increasing \(N\) is expensive in time. Doubling the column length doubles the elution time, solvent consumption, and pressure while only increasing \(R_s\) by 1.4. Likewise, reducing the particle diameter increases the resolution but may exceed the maximum allowable pressure.

Figure 6 Two-component chromatograms to illustrate the importance of peak-to-peak separation and peak widths on separation.

Figure 7 Significance of resolution values for two components with different relative concentrations.
The selectivity \( \alpha \) (thermodynamic factor) can be increased by changing columns to a different stationary phase or by imposing secondary equilibria through changes in mobile phase pH or the addition of complexing agents to the mobile phase, for example. In order to discuss the effect of selectivity changes, it is necessary to rearrange Equation (22) and solve for \( N \), as shown in Equation (23):

\[
N_{\text{req}} = 16R_s^2 \left( \frac{\alpha}{\alpha - 1} \right)^2 \left( \frac{k' + 1}{k'} \right)^2 \tag{23}
\]

If we assume \( R_s = 1.0 \) and \( k' = 2 \), then

\[
\begin{align*}
\alpha &= 1.01 & N_{\text{req}} &= 367000 \\
\alpha &= 1.05 & N_{\text{req}} &= 16000
\end{align*}
\]

Changing \( \alpha \) to 1.05 gives us a 96% reduction in required column efficiency which translates to a 96% reduction in column length, analysis time, solvent consumption, and solvent disposal. Changing selectivity is certainly the most efficient way to improve resolution. However, the cost of changing \( \alpha \) is in method development time.

Increasing the retention factor, \( k' \), can also increase resolution, particularly for early eluting compounds. This is done primarily by going to a weaker mobile phase. Looking at Equation (23) again, for \( R_s = 1.0 \), and \( \alpha = 1.05 \),

\[
\begin{align*}
0.1 & \quad N_{\text{req}} = 854000 \\
1.0 & \quad N_{\text{req}} = 28000 \\
10.0 & \quad N_{\text{req}} = 8500
\end{align*}
\]

While a 97% decrease in required column efficiency is calculated for changing \( k' \) from 0.1 to 1.0, another 70% decrease occurs for a \( k' \) change from 1.0 to 10.0. It is clear from Equation (22) that as \( k' \) becomes large, the resolution is unaffected by small changes in \( k' \). Changing \( k' \) to improve resolution thus has an upper limit of effectiveness at approximately \( k' = 10 \). This is illustrated in Figure 8.

### 2.4 Time Considerations

While any of the above methods will improve resolution, they are far from equal in terms of their effects on time. Recalling that \( t_r = t_0(1 + k') \), and \( H = L/N \), and realizing \( t_0 = L/v \), where \( v \) is the average flow velocity, then \( t_0 = HN/v \). So, \( t_r = (HN/v)(1 + k') \) and rearranging gives Equation (24):

\[
N = \frac{tv}{H(1 + k)} \tag{24}
\]

We can see that to double the resolution by increasing \( N \) (holding \( \alpha, k', H \) and \( v \) constant) requires a four-fold increase in time.

In the previous section we saw how changes in selectivity can improve resolution while decreasing analysis time. If we assume \( N = 10000 \) and \( k' = 2 \), and further if we could manipulate chromatographic conditions such that \( k'_2 \) would remain unchanged as we change selectivity, then by Equation (22) a change in \( \alpha \) from 1.01 to 1.05 would increase resolution from 0.2
LIQUID CHROMATOGRAPHY

8

LIQUID CHROMATOGRAPHY

We can see from Equation (25) then that with this improvement in resolution and the stated change in selectivity (holding \( H \) and \( v \) constant), that retention time would decrease by a factor of \( t_r^2 / t_r = 0.9 \), or 10%.

Figure 9 shows that the \( (k' + 1)^2/(k')^2 \) term in Equation (25) goes to infinity at both large and small values of \( k' \). Thus, in the effective range of \( k' \) values from 1 to 10 (holding \( H \) and \( v \) constant, and assuming \( \alpha = 1.05 \) and \( N = 10000 \)) the resolution would improve by a factor of 1.8 with a reduction in analysis time of 66%.

We know we can reduce analysis time by shortening the column, but we have a required efficiency necessary to separate the components in a mixture with the desired resolution. Assuming a well operating chromatograph yielding a reduced plate height of three, 10,000 plates can be generated with 10 \( \mu \)m diameter particles in 30 cm, with 5 \( \mu \)m particles in 15 cm, or with 3 \( \mu \)m particles in 9 cm. Assuming a solute with a retention factor of 2, the retention volume for these columns would be 9.0, 4.5 and 2.7 mL, respectively, and the peak base width would be 360, 180 and 108 \( \mu \)L, respectively.

2.5 Peak Capacity

Peak capacity (PC), defined in Equation (26), is the maximum number of components in a mixture that can be resolved with a resolution of one between the inert peak and the last peak.

\[
PC = 1 + \left( \frac{N^{1/2}}{4} \right) \ln(1 + k')
\]

(26)

As samples become more complex, the ability of a particular separation method to resolve all components decreases. A statistical study of component overlap has shown that a chromatogram must be approximately 95% vacant to provide a 90% probability that a given component of interest will appear as an isolated peak. This is shown graphically in Figure 10 where the probability of separation is plotted as a function of the system peak capacity for cases where the number of components varies from 10 to 70. A thorough discussion of resolving power is given by Martin et al.

Figure 10 Plots of the probability that all \( m \) sample components will be separated, \( P_b(p = m) \), as a function of the system peak capacity, \( n \), for the representative cases where \( m = 10, 30, 50 \) and 70. (Adapted from Martin et al.)

Elution chromatography can be carried out in either isocratic or gradient modes. In isocratic elution, the mobile-phase composition is held constant during separation of the sample, e.g. 60% v acetonitrile–water. In gradient elution, the mobile-phase composition will be varied during sample separation, e.g. changing from 0 to 100% v acetonitrile–water. Gradient elution requires special chromatographic equipment, as well as somewhat greater care on the part of the operator, but it has important advantages for many separations. Thus, in isocratic elution (Figure 1a), sample peaks tend to "bunch up" at the beginning of the chromatogram (often with decreased resolution) and to broaden at the end of the chromatogram (with reduced detection sensitivity). Gradient elution (Figure 1b), on the other hand, provides a more even spacing of peaks, similar widths throughout the chromatogram, and often a shorter run time. For these and other reasons, gradient elution is preferred for the separation of many samples.

1 INTRODUCTION

1.1 Characteristic Features

Gradient elution represents an alternative to isocratic separation and it is therefore useful to begin with a comparison of the two techniques. In isocratic elution, sample retention can be controlled by varying the composition of a mobile phase composed of a "weak" solvent A and a "strong" solvent B. An example is shown in Figure 2, for the separation of the o-dialkylphthalate sample of Figure 1 with a reversed-phase C18 column and mobile phases composed of water (A) and acetonitrile (B). An increase in % B from 50% B in Figure 2(a) to 70% B in Figure 2(b) results in decreased sample retention and a shorter run time. In isocratic separation as in Figure 2, the separation of any two adjacent peaks is critically dependent on % B. As the concentration of B increases and sample retention decreases, this in turn results in (1) reduced resolution, Rₛ, of the two bands, (2) decreased bandwidth and better detection sensitivity (taller peaks), and (3) a shorter run time as measured by the retention time, tᵣ, of the later-eluting band. For 50% B as mobile phase (Figure 2a), the separation of early bands C₂–C₄ is acceptable (Rₛ > 1.5), but later bands C₈–C₁₀ require a long time for their elution from the column and are wider and therefore less easily detected. For 70% B as mobile phase (Figure 2b), later bands C₈–C₁₀ leave the column in a much shorter time and are narrower and better detected; however, the separation of early bands C₂ and C₃ is poor (Rₛ = 0.6).

The isocratic separation of the o-dialkyl phthalate sample of Figures 1(a) and 2 is never completely satisfactory, regardless of the choice of mobile phase % B. The reason is that early bands require a weaker solvent (50% B in Figure 2a), while later bands benefit from a stronger solvent (70% B). The advantage of gradient elution for samples such as this is that each component of the sample can be eluted under conditions of optimum retention. Thus, in gradient elution all sample components are retained initially at the column inlet, because the starting mobile phase is usually quite weak and all bands initially have large values of k, the isocratic retention factor.
LIQUID CHROMATOGRAPHY

Figure 1 Separation of a mixture of \( \alpha \)-dialkyl phthalates by reversed-phase high-performance liquid chromatography (HPLC). Sample: alkyl homologs from dimethyl (C\(_2\)) to dipentyl (C\(_{10}\)). Conditions: 25 × 0.46-cm C\(_{18}\) column, acetonitrile (B)–water (A) mobile phases, 35 °C, 2 mL min\(^{-1}\). (a) Isocratic separation with 60% B, (b) gradient separation: 0–100% B in 12 min. Computer simulations\(^1\) based on data of Snyder et al.\(^2\) with \( N = 2000 \).

Figure 2 Isocratic separation of \( \alpha \)-dialkyl phthalate bands C\(_2\) and C\(_3\) as a function of % B. (a) 50% B, (b) 70% B. Other conditions as in Figure 1.

1.2 Advantages of Gradient Elution

Isocratic elution is a simpler procedure than gradient elution, and for this reason it is usually the preferred technique. However, there are several situations where gradient elution can be a better choice, as discussed below.

1.2.1 Samples with Widely Different Retention

If the sample of Figure 2(b) were limited to the later-eluting five components (C\(_6\)–C\(_{10}\)), the resulting separation with 70% B as mobile phase would be quite satisfactory, i.e. good resolution of all bands, good detectability for all bands, and a reasonable run time (14 min). The problem with the separation of the total sample (C\(_2\)–C\(_{10}\)) is that early bands (C\(_2\)–C\(_4\)) are weakly retained and later bands (C\(_8\)–C\(_{10}\)) are strongly retained. In isocratic elution it is desirable that all sample bands be eluted with a retention factor \( k \) that falls within a narrow range of values: e.g. \( 1 < k < 10 \). When this is not possible, as in the example of Figures 1 and 2, no isocratic mobile phase can provide a “good” separation of the sample. This is the most common reason for using gradient elution and it is sometimes referred to as the general elution problem. We will refer to samples such as that in Figures 1 and 2 as having a retention range that is too wide for isocratic elution.
1.2.2 “Dirty” Samples
Many samples contain minor amounts of strongly retained components that are not of interest to the analyst. Examples include extracts of plant or animal tissue, environmental samples, and synthetic organic reaction mixtures. The repeated isocratic separation of such samples can result in a gradual accumulation of these “late eluters” on the column, with corresponding changes in sample retention, loss of column efficiency, and degradation of the baseline. For this reason, a frequent cleansing of the column may be required, as by washing the column with a strong solvent (e.g. 100% B). When gradient elution is used for the analysis of such samples, the column will be cleaned automatically by the strong mobile phase at the end of the gradient.

1.2.3 “Scouting” Runs During Method Development
The use of an initial gradient separation can be a valuable start to the development of a final HPLC method. Conditions for optimized retention can be estimated prior to the first experimental run (see section 3.1), such that most sample components are partially resolved and some idea of sample complexity can be formed. Furthermore, minor components that elute either early or late are
often overlooked during isocratic separation, whereas the presence of such components is much more obvious in a gradient run (see Figure 4 and note peaks A and G marked by an asterisk). Once an initial gradient run has been obtained, it is possible to estimate reliably whether further experiments (and the final method) should be carried out under isocratic or under gradient conditions. Figure 4, which involves a gradient time $t_G = 20$ min (see Figure 3a) can be used to illustrate this procedure. As a first example, assume that only the major peaks B–F are of interest. Next, determine the difference in retention times for the first (B) and last (F) peaks, equal to $14.5 - 11.8 = 2.7$ min. Multiply this by the gradient rate (95% per 20 min = 4.75% min$^{-1}$). If the elution range (2.7 min $\times$ 4.75% min$^{-1}$ = 12.8%) is less than 25%, isocratic elution will be preferred. If this ratio is larger, then gradient elution generally will be advantageous. In this latter example, isocratic elution is recommended. Alternatively, assume that peaks A–G are of interest. For this case, the retention time difference is $16.3 - 6.3 = 10$ min, and the elution range is $10$ min $\times$ 4.75% min$^{-1}$ = 47.5%. For the separation of peaks A–G, gradient elution would be a better choice. For samples where isocratic elution is preferred, the initial gradient run can also provide an estimate of isocratic % B for good sample retention ($1 < k < 10$). Thus avoiding a need for trial-and-error adjustments of % B in later runs.

1.3 Linear versus Nonlinear Gradients

Figure 3(a–e) illustrates different gradient shapes that modern equipment is able to deliver, as desired by the user. While linear gradients (Figure 3a) are generally preferred, nonlinear gradients can sometimes reduce separation time, improve sample resolution, and/or increase detection sensitivity. Segmented gradients (as in Figure 3d) are generally preferred with respect to other nonlinear gradient shapes (e.g. Figure 3b and c), because they are easier to optimize for a given sample. A common application of segmented gradients is the use of a very steep end-segment (or a step gradient) to 100% B in order to clean the column before the next injection. Less often, segmented gradients are useful in optimizing different parts of the chromatogram (see section 3.2). Thus, early peaks may prefer a steep gradient, while later peaks are better separated with a flat gradient (or vice versa).

1.4 Equipment Used for Gradient Elution

An HPLC system equipped for gradient elution must provide a means for creating gradients of various shapes, as in Figure 3. Typically, this is achieved by an electronic controller that varies the flow of two solvents A and B into a mixing chamber ("gradient mixer"), from which the mobile phase A–B passes into the column. This is illustrated in Figure 5(a) for a so-called “high pressure” mixing system. Solvents A and B are contained in reservoirs that feed separate pumps. The electronic controller can be programmed by the user to specify the desired gradient in terms of starting % B, final % B, gradient time $t_G$ (or % B min$^{-1}$), and shape. The total flow rate is usually maintained constant during the gradient. Once the gradient is programmed and separation is begun, the controller determines the relative flow of solvents A and B to the mixer as a function of time. This in turn generates gradients as in Figure 3(a–e). Typically, sample injection initiates the start of the gradient.

There are two general designs of gradient equipment, corresponding to the high-pressure mixing system of Figure 5(a), or the low-pressure mixing system of Figure 5(b). In the latter system, the gradient is formed before the pump and only one pump is required to deliver the gradient to the column. High- and low-pressure systems are each widely used and are equally capable of reliable operation.

High-pressure mixing systems have a simple design, with the flow rate of the two pumps varying to provide the desired proportion of solvents A and B. Mixing takes place on the high-pressure side of the pump, minimizing outgassing problems (see section 4.3) and usually giving a smaller dwell volume (see section 4.2).

Low-pressure mixing systems require only one pump and may accommodate up to four solvents in many designs. Because solvents are mixed at atmospheric pressure, outgassing can compromise pump reliability.
and the passage of the mixed solvents through the pump usually results in a larger dwell volume.

2 THEORY

Gradient elution involves additional experimental options when compared with isocratic separation, and for this reason is a more complicated technique to use and to understand. Fortunately, it is possible to describe gradient elution in virtually the same way as isocratic elution. Since most chromatographers are familiar with isocratic elution, it is therefore possible to achieve a similar understanding of gradient elution with little extra effort. In the following discussion, mobile phase composition as defined by %B will also be referred to as φ, the volume-fraction of B in the mobile phase A–B; φ = 0.01 × (% B).

2.1 Band Migration During Gradient Elution

In gradient elution the sample is typically (but not always) strongly retained at the beginning of the gradient, i.e. as for isocratic elution with the starting mobile phase. As the mobile phase becomes stronger during the gradient (larger φ or %B), sample retention decreases (as in Figure 2) and eventually the least-retained band X in the sample begins to migrate through the column. This process is illustrated in Figure 6 for the first (X) and last (Z) bands in the chromatogram. The solid curve labeled “X” shown in Figure 6(a) shows the migration of the band from the column inlet to outlet during the gradient. The accompanying dashed curve describes the instantaneous isocratic retention k at the same location in the column occupied by band X. Because φ increases during the gradient, k decreases, and band migration accelerates as a function of time. At some time t_X (equal to the retention time t_R of the band), compound X leaves the column and appears as the first band in the chromatogram.

In gradient elution it is possible to define an average retention factor k^, corresponding to an isocratic value k. Likewise, it is possible to define an average mobile phase composition φ = φ^*. Values of k^ and φ^* correspond to values of k and φ when the band has migrated halfway through the column (“band migration” = 0.5 in Figure 6). In the example of Figure 6, k^ = 2 for band X. Other sample components will migrate through the column at later times, as illustrated by the last band Z.

Figure 6 Band migration during gradient elution. (a) Solid curve, band migration; dashed curve, instantaneous value of k. (b) Resulting chromatogram showing first (X) and last (Z) peaks. See text for details. (Reprinted with permission from Snyder et al.8)
in Figure 6. These later-eluting bands can be thought of as remaining stationary at the head of the column (very large isocratic \( k \)) until a sufficiently strong mobile phase arrives, causing them to move through the column. Because of the similar migration pattern (solid curves in Figure 6) for different sample components during gradient elution, values of \( k^* \) generally will be approximately equal for each band and therefore bandwidths in gradient elution tend to be similar for all sample components (see Figure 2b).

2.2 Linear Solvent Strength Model

Reversed-phase retention usually can be approximated by Equation (1)

\[
\log k = \log k_w - S\phi
\]  

(1)

Here, \( \log k \) varies linearly with mobile phase composition \( \phi; k_w \) refers to the extrapolated value of \( k \) for water as mobile phase (\( \phi = 0 \)), and \( S \) is a constant for a particular sample compound when only \( \phi \) varies. If a linear gradient is chosen (as in Figure 3a), Equation (2) applies

\[
\phi = \phi_0 + (\phi_f - \phi_0) \frac{t}{t_G}
\]  

(2)

where \( \phi_0 \) and \( \phi_f \) refer to the initial and final \( \phi \) values, and \( t \) is time. Combination of Equations (1) and (2) then gives Equation (3)

\[
\log k = (\log k_w - S\phi_0) - \frac{S(\phi_f - \phi_0)}{t_G}t = A - Bt
\]  

(3)

Here, \( A \) and \( B \) are constants for a sample compound, and \( \log k \) varies linearly with time \( t \). We will refer to gradient separations which can be approximated by Equation (3) as linear solvent strength (LSS) gradients. Gradients of this type can be described in the same terms used for isocratic elution, and for this reason LSS gradients provide a convenient basis for understanding gradient separations. The LSS model can also provide a more qualitative (but still useful) description of other HPLC methods, e.g. ion-exchange or normal-phase chromatography. For a more detailed discussion of LSS theory, see Snyder and Dolan.\(^8\)

2.3 Retention and Bandwidth in Gradient Elution

The average retention of a band in reversed-phase gradient elution is given for LSS gradients as Equation (4)

\[
k^* = \frac{0.8747F}{V_m \Delta\phi S}
\]  

(4)

where \( F \) is flow rate, \( V_m \) is the column dead volume, and \( \Delta\phi \) equals \( (\phi_f - \phi_0) \), the change in \( \phi \) during the gradient. For reversed-phase HPLC, an average value of \( S \approx 4 \) can be assumed for compounds with molecular weights \( < 500 \text{ Da} \).\(^8\) Just as in isocratic elution it is desirable for \( 1 < k < 10 \), so in gradient elution it is advantageous for \( 1 < k^* < 10 \). However, in gradient elution with a linear gradient the value of \( k^* \) will be similar for every sample band and an intermediate value of \( k^* \), e.g. \( k^* = 5 \), is a good initial choice.

Prior to any experimental runs, preferred starting conditions for a gradient separation can be selected, such that \( k^* \approx 5 \). As an example, assume that a column and flow rate are selected for the same reasons as in isocratic separation (to provide acceptable column back-pressure and a reasonable run time), e.g. a 15 × 0.46 cm C\(_{18}\) column at 2.0 mL min\(^{-1}\). For columns with an internal diameter of 0.46 cm, the column dead volume \( V_m \) can be approximated by 0.1 times the column length in centimeters, or 1.5 mL in this example. Similarly, for a sample that has not previously been separated by HPLC, it is wise to use a full-range gradient (e.g. 0–100% B) so that \( \Delta\phi = 1.0 \). Full-range gradients can provide reasonable separation for samples that are either weakly or strongly retained. Referring to Equation (4), the only variable so far not specified is gradient time \( t_G \); Equation (4), with \( S \approx 4 \), can be rearranged to solve for the necessary gradient time to achieve a value of \( k^* = 5 \), Equation (5):

\[
t_G \approx \frac{20 V_m \Delta\phi}{F}
\]  

(5)

For the column \( (V_m = 1.5 \text{ mL}) \), flow rate \( (2.0 \text{ mL min}^{-1}) \), and gradient range \( (\Delta\phi = 1) \) assumed in this example, a gradient time of 15 min should result in \( k^* \approx 5 \). This would be a good choice of conditions for the first experiment in HPLC method development.

Baseline bandwidth, \( W \), in isocratic separation is given from the definition of column plate number, \( N \), as, Equation (6)

\[
W = \left( \frac{16}{N} \right)^{1/2} \frac{1}{t_r} = 4t_0 \frac{k + 1}{N^{1/2}}
\]  

(6)

For gradient separations, a similar equation can be derived from the LSS model,\(^8\) where \( k \) in Equation (6) is replaced by the value of \( k \) in gradient elution when the band leaves the column: \( k^* / 2 \). This gives for gradient elution, Equation (7)

\[
W = 4t_0 \left( \frac{k^*}{2} + 1 \right) N^{-1/2}
\]  

(7)

Thus, bandwidth in gradient elution is very similar to that in isocratic separation, except that for “corresponding conditions” \( (k = k^*) \), bandwidths in gradient elution are predicted to be smaller. However, Equation (7)
ignores the fact that a gradient tends to compress the sample band further, because the band tail leaves the column in a higher % B than the band front. On the other hand, this effect (which tends to sharpen bands in gradient versus isocratic elution) is compensated by another phenomenon, “anomalous band broadening” as discussed by Snyder and Dolan.\(^8\) As a result, Equation (6) is in most cases an adequate approximation for bandwidth in gradient elution.

2.4 Resolution in Gradient Elution

Resolution in gradient elution is conveniently expressed by a relationship that can be derived from the LSS model, Equation (8):

\[
R_s = \frac{1}{4}(\alpha - 1)\sqrt{N/k^* + 1} \tag{8}
\]

Equation (8) is of identical form as for isocratic elution (where \(k\) replaces \(k^*\) in Equation 8). Here, \(\alpha\) is the separation factor, and both \(\alpha\) and \(N\) in Equation (8) are average quantities measured when the band is at the column midpoint. Equation (8) is useful for gradient elution method development, where separation can be systematically improved by successive changes in sample retention, \(k^*\), separation selectivity as measured by \(\alpha\), and column efficiency \(N\). This is further illustrated in section 3.

3 SELECTING CONDITIONS FOR GRADIENT ELUTION

HPLC method development consists of experiments that can be used to select conditions for adequate separation, a process that is sometimes referred to as optimizing the separation. A detailed discussion of method development for gradient elution is given by Snyder et al.,\(^6\) where it is shown that essentially the same procedure can be used for both gradient and isocratic methods. Sample retention as measured by \(k^*\) or \(k\) is the most easily optimized and usually is adjusted first. Selection selectivity as measured by \(\alpha\) is often of critical importance and usually is considered next. Changes in selectivity (\(\alpha\)) are essential whenever bands overlap in the chromatogram. Changes in column efficiency (\(N\)) are achieved by varying column length, particle size, and flow rate, and usually are carried out after optimizing sample retention \(k^*\) and separation selectivity \(\alpha\).

3.1 Effects of Gradient Steepness, Range, and Shape

Changes in gradient steepness, range, and shape mainly affect sample retention \(k^*\).

Figure 7 Effect of gradient time (\(t_G\)) and steepness (% B min\(^{-1}\)) on separation. Herbicides sample, 25 × 0.46-cm C18 column, methanol–water gradients. (a) 0–100% B in 5 min, 20% min\(^{-1}\), \(k^* = 0.7\); (b) 0–100% B in 20 min, 5% min\(^{-1}\), \(k^* = 3\); (c) 0–100% in 100 min, 1% min\(^{-1}\), \(k^* = 14\). (Reprinted with permission from Snyder et al.\(^6\))

3.1.1 Gradient Steepness

Gradient steepness is defined as the change in % B per minute during the gradient (or \(\Delta\Phi/t_G\)). From Equation (4), \(k^*\) is seen to vary with \(t_G/\Delta\Phi\), i.e. inversely as gradient steepness. As \(k\) increases in isocratic separation (Figure 2), overall separation (\(R_s\)) is seen to improve, run time increases, and bands become wider so that detection sensitivity decreases. Exactly the same results are expected in gradient elution when \(k^*\) increases. An increase in \(k^*\) is most conveniently effected by increasing gradient time, \(t_G\), equivalent to decreasing gradient steepness. This is illustrated in Figure 7 for the separation of a herbicide sample, where the gradient time is changed from 5 min (a) to 20 min (b) and 100 min (c), corresponding to a change in \(k^*\) from 0.7 to 3 to 14. It is apparent in Figure 7 that sample resolution increases from Figure 7(a) to Figure 7(c); this is better seen for the
three bands at the end of the chromatogram (bracket and arrow). For the five-minute gradient Figure 7(a), the three bands overlap completely. When the gradient time is increased to 20 min Figure 7(b), the last band is separated to baseline, and the other two bands are partly resolved. For the 100-minute gradient Figure 7(c), all three bands are adequately resolved. At the same time, when gradient time is increased, all bands (except the solvent peak at 1.5 min) broaden and, because band area is constant, corresponding peak heights decrease (reduced detection sensitivity).

We can summarize Figure 7 as follows. Resolution is inadequate for the five-minute gradient in Figure 7(a), where \( k^* = 0.7 \); similarly, for the 100-minute gradient of Figure 7(c), where \( k^* = 14 \), run time is excessive and detection sensitivity is poor. These results are typical of separations where \( k^* < 1 \) or \( k^* > 10 \). In general, an intermediate gradient time will be optimum, and the 20-minute gradient of Figure 7(b), for which \( k^* = 3 \), comes close in this respect. However, three band pairs are poorly resolved, so an increase in gradient time to 50 min (\( k^* = 7 \)) is a better choice, as seen in Figure 8(a). Although bands 7/8 are separated with marginal resolution (\( R_s = 1.1 \)), this is a reasonable result at this stage in method development. It should be possible to improve the separation of bands 7/8 by a later change in separation selectivity (see section 3.2).

### 3.1.2 Gradient Range

Once an optimum value of gradient steepness is determined as in Figure 8(a) (2% B min\(^{-1}\)), a change in gradient range (values of \( f_0 \) and \( f_f \)) is the next step. The primary goal of changing the initial and final % B of the gradient is to save time. Thus, in the separation of Figure 8(a), there is an empty space in the chromatogram (devoid of peaks) between 4 and 19 min which represents wasted time. This wasted time can be reduced by an increase in the initial value of % B (\( f_0 \)). Figure 8(b) shows the result of an increase in initial % B from 0 to 40%. When changing the gradient range in order to reduce run time, it is important to keep gradient steepness (2% B min\(^{-1}\) in this example) constant to keep \( k^* \) constant. So gradient time is reduced from 50 to 30 min in the example of Figure 8(b). The overall appearance of the chromatogram is nearly identical between the two runs of Figure 8(a) and (b), which is typical when changing gradient range while maintaining gradient steepness constant. A slight loss of resolution (\( R_s = 0.7 \)) is seen with critical band-pair 7/8, but this is acceptable. The result of a further increase in initial % B to 60% is shown in Figure 8(c), with a further decrease in gradient time to 20 min. However, now the initial % B of the gradient is too large; early bands are pushed together with a serious loss of resolution (\( R_s = 0.7 \)). A more reasonable compromise is shown in Figure 8(d), where 50% B as initial mobile phase results in marginal resolution (\( R_s = 0.9 \)), but run time is reduced to only 25 min. The choice of Figure 8(d) as "best" assumes that later changes in separation selectivity will be able to restore the resolution of bands 7/8 to an acceptable value (e.g. \( R_s > 1.5 \)).

The last band in Figure 8(d) leaves the column before the gradient has ended, which represents a further opportunity to reduce wasted time and shorten the run time. This is illustrated for the same separation in Figure 9(a), where the end of the gradient is indicated by an arrow. A general goal in selecting the final % B for the
gradient is to terminate the gradient at the time the last band is eluted. In the present case, the last band elutes when the mobile phase leaving the column is 80% B, suggesting a gradient range of 50–80% B and a gradient time of 15 min. This separation is shown in Figure 9(b). At this point, the run time of the original gradient (0–100% B in 50 min) has been shortened from 43 min (Figure 8a) to 18 min (Figure 9b), with only a minor loss in resolution. If the final % B is further reduced to 70% (Figure 9c) or 60% (Figure 9d), the result is an increase in run time and a broadening of later bands with loss in detection sensitivity, as a result of elution of bands after the gradient ends. These bands show isocratic retention behavior, as seen by broader peaks as retention increases. Elution of

---

**Figure 9** Effect of final % B ($f_f$) on gradient separation. Herbicides sample, conditions (other than final % B and gradient time) as in Figure 8(d). (a) 50–100% B in 25 min (2% min$^{-1}$), (b) 50–80% B in 15 min (2% min$^{-1}$), (c) 50–70% B in 10 min (2% min$^{-1}$), (d) 50–60% B in 5 min (2% min$^{-1}$). (Reprinted with permission from Snyder et al.)
sample bands after the gradient is always disadvantageous and should be avoided where possible.

3.1.3 Gradient Shape

Linear gradients are generally preferred and should always be tried first. After gradient retention has been adjusted as in Figures 7–9, a change in gradient shape can sometimes be used to improve the separation further. A typical example is shown in Figure 10, where the linear gradient in Figure 10(a) results in a rather long run time, and later bands are widely spaced in the chromatogram (i.e. are overseparated). In cases like this, an increase in gradient steepness toward the end of the chromatogram can result in faster elution of later bands without an unacceptable decrease in resolution. This is illustrated in Figure 10(b), where run time has been reduced from 74 to 60 min, without compromising the separation of later bands. Because gradient steepness is the same in Figure 10(a) and (b) prior to 48 min (the breakpoint in the gradient of Figure 10b), the separation of peaks (#1–15) eluting before 48 min is identical in Figure 10(a) and (b).

A change in gradient steepness also can be used to improve sample resolution, when separation selectivity varies with gradient steepness. This is illustrated in the example of Figure 11, discussed further in the following section.

3.2 Control of Band Spacing

After gradient retention has been optimized as in Figures 7–9, the next step is a change in separation selectivity as a means of avoiding overlapping bands. With only minor changes, the same approach can be used in both gradient and isocratic elution in order to optimize selectivity and band spacing. Table 1 lists some of the variables that are commonly used to change band spacing. Because there are several ways to change selectivity and because improvements in band spacing are unpredictable, optimizing band spacing ($\alpha$) usually requires more effort than optimizing either retention ($k$) or column efficiency ($N$).

Some variables (first column in Table 1) affect every kind of sample, whereas other variables (second column of Table 1) only affect samples that are ionizable, i.e. containing acids and/or bases. The ability of a change in the variables of Table 1 to change band spacing (and improve resolution) decreases generally in going down each list; i.e. B-solvent type $>$ column type $>$ gradient steepness $>$ temperature, and pH $>$ ion-pairing $>$ buffer or additive concentration. Also, ionizable samples generally show larger changes in band spacing when a particular variable is changed. On the other hand, the use of gradient steepness and temperature to change selectivity is particularly convenient and is free from
GRADIENT ELUTION CHROMATOGRAPHY

Figure 11(a) and (b) shows separations for gradient times of 7 and 20 min. In the steeper gradient of Figure 11(a), band-pair 3/4 is “critical”, i.e., is the least resolved. In the shallower gradient of Figure 11(b), band-pair 14/15 is critical. This suggests that an intermediate gradient time will provide a better overall separation, as is seen in Figure 11(c) for a gradient time of 12.5 min. Because early bands 3/4 prefer a shallower gradient, while later bands 14/15 prefer a steeper gradient, an even better separation is predicted for a segmented gradient which is shallow initially and steep at the end. This is confirmed in the separation of Figure 11(d), where all bands are separated to baseline (\( R_s \geq 1.7 \)). This example illustrates one of the (few) unique differences between isocratic and gradient elution. In isocratic elution, because experimental conditions cannot be changed during the separation, maximum resolution for the critical band-pair(s) usually represents a compromise for the overall sample, as in Figure 11(c) for this gradient separation. However, because conditions can be changed during gradient elution, it is possible to optimize conditions separately for early-eluting with respect to late-eluting bands.

Figure 12 shows a similar change in band spacing for the separation of a mixture of substituted phenols. The separation in Figure 12(a) with an acetonitrile–water gradient provides baseline separation of all compounds except bands 8/9. A change in B-solvent from acetonitrile to methanol in Figure 12(b) results in the separation of band-pair 8/9, but with some loss in resolution of bands 2 and 3. In Figure 12(c), the use of a gradient that begins with 20% acetonitrile–water and ends with 100% methanol provides the best overall separation, similar to the example of Figure 11(d).

A final example of selectivity control in gradient elution is shown in Figure 13. Here, five synthetic peptides are separated with acetonitrile–water gradients, with a variable amount of TFA added to the mobile phase as a combined buffer and ion-pairing agent. A change in the concentration of an ion-pairing agent can provide very large changes in band spacing, when the sample contains compounds whose molecular charge varies widely (as in the present case, where the band numbering in Figure 13 indicates the net positive charge on each compound). An examination of these six chromatograms shows that the addition of 0.05% TFA to the mobile phase provides the

various problems that can arise during the control of selectivity.⁶ For this reason, the simultaneous variation of both temperature and gradient steepness is especially useful for controlling selectivity during gradient elution method development (see section 3.4).

Changes in gradient steepness, as in Figure 7, are usually the first step in gradient method development. During these experiments, changes in band spacing may be observed which can be exploited for optimizing selectivity. This is illustrated in Figure 11 for the separation of a mixture of 16 PAHs of environmental concern.
3.3 Effects of Column Dimensions, Particle Size and Flow Rate

Varying the column plate number $N$ in either isocratic or gradient method development is usually best delayed until after retention ($k$ or $k^*$) and selectivity ($\alpha$) have been

---

**Figure 12** Effect of B-solvent on separation of a mixture of phenols. Conditions: $30 \times 0.42$-cm C$_{18}$ column; gradients as in figure; $1.0 \text{ mL min}^{-1}$; ambient. best overall separation. Because bands 1 and 2a are the critical pair in this chromatogram, it can be predicted that a slight increase in TFA (to 0.06 or 0.07%) should provide an even better resolution for the critical band pair.

**Figure 13** Separation of basic peptides as a function of TFA concentration. Conditions: $25 \times 0.46$-cm C$_{18}$ column; A-solvent, water plus indicated %-TFA; B-solvent, acetonitrile plus indicated %-TFA; gradient from 0% B at 1% min$^{-1}$; $1.0 \text{ mL min}^{-1}$; 26°C. (Reprinted with permission from Guo et al. [12] J. Chromatogr., Copyright (1987) with permission of Elsevier Science.)
optimized. At this point in method development, \( N \) can be increased for an increase in sample resolution. Also, since an increase in \( N \) usually requires a longer run time, a decrease in \( N \) can be used to save separation time, if sample resolution is greater than necessary. A change in \( N \) can be achieved by a change in “column conditions”: column length \( L \), particle size of the column packing \( d_p \), or flow rate \( F \). An increase in \( N \) usually results from an increase in \( L \) or a decrease in \( d_p \) or \( F \). (Changes in \( N \) with \( F \) are more pronounced for larger (e.g. 10-\( \mu \)m \( d_p \)) particle packings, and may be of little practical benefit for 3–5-\( \mu \)m \( d_p \) materials.)

In isocratic separation, a change in \( L \) or \( F \) has no effect on values of \( k \) or \( \alpha \), so optimizing column conditions can be carried out independently of changes in \( k \) or \( \alpha \). That is, further improvements in an isocratic separation can be made without worrying about any corresponding changes in \( k \) or \( \alpha \). Because \( k^* \) in gradient elution depends on both column size (\( V_m \)) and \( F \) (Equation 4), changes in \( k^* \) and \( \alpha \) can result when varying \( L \) or \( F \). This is illustrated in Figure 14, for the separation of a peptide sample (trypsin digest of the protein myoglobin). Entire chromatograms are shown in Figure 14(a) for two different flow rates (0.5 and 1.5 mL min\(^{-1} \)), other conditions being the same. Expanded portions of each chromatogram (brackets, arrows) are reproduced in Figure 14(b) for easier visibility. It is seen in Figure 14(b) that the change in flow rate from 0.5 to 1.5 mL min\(^{-1} \) results in major changes in band spacing: coelution of bands 5 and 5a at 1.5 mL min\(^{-1} \), coelution of bands 6 and 6a at 0.5 mL min\(^{-1} \), and a reversal of the retention of bands 6b and 7. Changes in selectivity such as this, as a result of varying \( F \) or \( L \), would not occur in isocratic separation.

Because a change in column conditions generally is delayed until after band spacing has been optimized, further changes in band spacing when optimizing \( N \) are undesirable. Changes in \( \alpha \) similar to those of Figure 14 can be avoided when changing column conditions by maintaining \( k^* \) constant. Referring to Equation (4) (and noting that \( V_m \) is proportional to \( L \)), if \( k^* \) is to remain constant while varying \( L \) or \( F \), then it is necessary to maintain \( (t_G F/L) \) constant. This can be achieved by varying gradient time in inverse proportion to \( F \) and in direct proportion to \( L \).

### 3.4 Computer Simulation

The theory of reversed-phase gradient elution has now been developed to a point where it is possible to predict retention times, \( t_R \), and bandwidths, \( W \), as a function of experimental conditions, when the parameters of Equation (1) (\( k_w \) and \( S \)) are known. Thus, Equation (9)

\[
\log \frac{2k_0}{k^*} + 1 + t_o + t_D \tag{9}
\]

Here, \( t_o \) is the column dead time, \( k_0 \) is the value of \( k \) at the start of the gradient, and \( t_D \) is the equipment hold-up or “dwell” time (see section 4.2). Similar predictions of gradient retention time can be made for ion-exchange separation.\(^{(14,15)}\) For the case of reversed-phase gradient elution, two experimental runs suffice to determine \( k_w \) and \( S \) for each compound in the sample.\(^{(8)}\) If these values are entered into computer simulation software (Snyder et al.,\(^{(2)}\) and Snyder et al.\(^{(6)}\) page 448–452), it is then possible to predict separation for

### Table 2

various changes in conditions as summarized in Table 2. Thus, a small number of experiments during method development allow the prediction of a large number of separations, leading to the speedy optimization of the various conditions of Table 2. Computer simulation is also useful for studying the general consequences of different changes in conditions, as in the examples (computer simulations) of Figures 7–9.

Computer simulation has recently been extended\cite{16,17} to allow the simultaneous optimization of temperature and gradient steepness, in addition to the other conditions of Table 2. This is illustrated in Figure 15 for the separation of a mixture of 13 commercial herbicides. Predictions of separation as in Figure 15 require four experimental runs, where two different temperatures $T$ and gradient times $t_G$ are used: 30 and 40°C and 40 and 120 min in this example. Following entry of the resulting data (retention times, band areas, experimental conditions) into the computer simulation program, various predictions as in Table 2 are possible. Usually it is desirable to request a resolution map, which plots critical resolution (for the least resolved band

Figure 15 Computer simulation for the optimization of the separation of 13 herbicides. Conditions: 25 x 0.46-cm C$_{18}$ column, 20–95% acetonitrile–buffer gradients, 1.0 mL min$^{-1}$. Chromatogr., Copyright (1998) with permission from Elsevier Science.)
pair) as a function of gradient time and temperature in this example. Figure 15(a) shows the resulting resolution map, with maximum resolution indicated for 34 °C and a 90-min gradient time. The predicted separation is shown in Figure 15(b), and the experimental confirmation of this prediction is given in Figure 15(c). Retention time predictions by means of computer simulation are typically accurate to better than 1%, as in the example of Figure 15.

4 “NONIDEAL” EFFECTS IN GRADIENT ELUTION

Apart from its somewhat greater complexity, as summarized in sections 1–3, gradient elution is subject to some additional problems which are absent (or uncommon) in the case of isocratic elution. The effective use of gradient elution for practical applications requires an awareness of these “non-ideal” effects (see Snyder et al.\(^6\)) for further details.

4.1 Nonequilibration of the Column

When the mobile phase is changed in isocratic elution, it is necessary to flush the column with a sufficient volume of the new mobile phase to equilibrate the column. However, once the column is equilibrated, samples can be successively injected without further concern for column equilibration. In the case of gradient elution, the mobile phase at the end of each separation differs from the beginning mobile phase for the next sample injection. This requires that the column be flushed with a sufficient volume of the initial mobile phase to achieve equilibration of the column, prior to injection of the next sample. Although column equilibration typically can be achieved by flushing with 5–10 column volumes of the starting mobile phase, the exact intersample flush volume must be experimentally confirmed for each gradient method. Equilibration volume can be checked by selecting a starting volume (e.g. 5 column volumes) and making a run. Then the equilibration volume is increased (e.g. to 10 column volumes) and the run is repeated. The equilibration volume will be satisfactory when further increases in volume cause no change in sample retention (poor equilibration generally appears as shorter retention times, especially for early eluting peaks). Because of the need for column equilibration between each sample injection, total run time in gradient elution usually is somewhat greater than for isocratic separation. However, extremely fast gradient separations (e.g. 1–2 min run times) are nevertheless possible.\(^18\)

Another practical consequence of column equilibration in gradient elution regards the choice of the initial % B. At very high water content (e.g. >97%), the bonded phase on reversed-phase columns tends to undergo a configuration change or “collapse”. Resolvation of the phase following collapse can be slow when compared to normal column equilibration, further extending the turnaround time for routine operation. The magnitude of this equilibration problem varies with the stationary phase and sample type. It is prudent to use ≥5% B as the starting solvent for gradient elution to avoid this phenomenon. Thus, most workers prefer 5–100% B gradients over 0–100% B.

4.2 Gradient Delay and Rounding

The design of the equipment used for gradient elution (Figure 5) results in some distortion of the gradient delivered to the column, as illustrated in Figure 3(f). Thus, following the combination of A and B solvents, the resulting mobile phase must pass through the gradient mixer, various connecting lines and filters, the autosampler, and (in the case of low-pressure gradient mixing) the pump. As a result of this movement of mobile phase through the system, the gradient will be delayed and to some extent dispersed or rounded. This means that the programmed gradient can differ significantly from the actual gradient. Because these differences are peculiar to each equipment design, gradient methods tend to be less transferable than isocratic methods.

The main effect of equipment differences on separation is usually the result of differences in the hold-up or “dwell” volume, i.e. the volume swept out by the mobile phase as it passes through the mixer onto the column. If the equipment dwell volume is known, it is possible to predict its effect on separation by means of computer simulation (see section 3.4). In most cases, minor changes in gradient conditions (initial % B, gradient steepness) can be used to adjust for differences in dwell volume.

4.3 Equipment and Baseline Problems

The added complexity of the equipment used for gradient elution can create additional problems that are less common or nonexistent with isocratic systems. In practice, however, many workers use the same equipment for isocratic as for gradient separations because of the convenience of on-line mixing. The potential problems outlined here can be overcome, for the most part.

4.3.1 Mobile Phase Outgassing

When organic solvent/water blends are prepared, the resulting mixture usually has a lower capacity for dissolved air than the pure solvents. When solvents are mixed on-line to form the gradient, outgassing can occur. If these bubbles pass through the pump, check-valve failure, pressure fluctuations, and flow variation can occur. Outgassing tends to be more of a problem
for low-pressure mixing systems because the solvents are mixed at (or below) atmospheric pressure. High-pressure mixing tends to compress the air, keeping it in solution, so fewer bubble problems are experienced. For both types of equipment, degassing, as with helium sparging, will give more reliable operation.

Sometimes air bubbles are generated when the mobile phase returns to atmospheric pressure at the end of the column. If these bubbles pass through the detector, baseline disturbances result. In addition to mobile phase degassing, the use of a back-pressure regulator after the detector usually will alleviate detector bubble problems.

4.3.2 Proportioning Problems

The actual gradient reaching the column differs from that programmed into the system controller. As illustrated in Figure 3(f), rounding at the ends of the gradient occurs because of the washout characteristics of the equipment. Further distortion of the gradient can occur if the equipment is not operating properly. An easy way to check this is to place a UV (ultraviolet)-absorbing solute in the B-reservoir and run a gradient with a short piece of tubing replacing the column. For example, water can be used for the A solvent and 0.1% acetone in water as the B solvent, with a 0–100% B gradient run over 20 min. If the gradient is straight in the middle, as in Figure 3(f), the equipment appears to be operating properly. If the gradient is bowed or an offset is observed mid-gradient, the system needs to be serviced.

Proportioning accuracy can be checked by programming a series of isocratic steps, as in Figure 3(e), for example 10% steps over a 0–100% B range, using the acetone–water mobile phase. The steps should approach stair steps and be even in size, as in Figure 16(b). If uneven or distorted steps are observed, as in Figure 16(a), equipment service is required. Most manufacturers specify proportioning accuracy of ±0.5–1.0% B; from a practical standpoint, ±1.0% (as in Figure 16b) is satisfactory if the steps are even and well-shaped.

4.3.3 Baseline Drift

Baseline drift in gradient elution is caused by changes in temperature or mobile phase absorbance. Temperature drift should not be a problem if the column is operated in a column oven – this is a wise choice for isocratic methods as well, because retention and selectivity are influenced by temperature.

Baseline drift in temperature-controlled systems may be observed when the A and B solvents have different UV absorbance (assuming UV detection). This is illustrated in Figure 17. Two general trends are observed. First, the organic solvents used for reversed-phase usually have more absorbance than water and the absorbance varies with the solvent. This is seen for the larger drift with the water–methanol gradient of Figure 17(a) when compared to water–acetonitrile (Figure 17b). Second, as the detection wavelength is reduced, the drift is magnified (compare Figure 17c and 17a). As long as the baseline drift is acceptable (i.e. the baseline stays on-scale), most data systems can successfully integrate peaks, so quantitation should be satisfactory. The lower background absorbance of acetonitrile at low wavelengths (Figure 17a versus Figure 17b) makes it the solvent of choice for low-wavelength gradient applications. An additional advantage of acetonitrile over methanol for gradient elution is its lower viscosity when mixed with water. This results in substantially lower column back pressure, allowing higher flow rates and thus shorter run times.

4.3.4 Baseline Artifacts

One problem with gradient elution that is not experienced with isocratic separation is the presence of background peaks in the gradient. A blank gradient always should
be run prior to a series of samples to determine the magnitude of background peaks. In extreme cases, a blank baseline can appear as shown in Figure 18(a). The observed peaks represent contaminants in the water phase that collect at the head of the column during equilibration and then elute off as if they were sample components when the gradient is run. Use of a better quality of water (Figure 18b) usually will remove most or all of the unwanted peaks. In particularly difficult cases, on-line cleanup can be used to advantage. Baseline artifacts will be minimized if HPLC-grade solvents and additives are used.

4.3.5 Buffer Precipitation

Precipitation of buffers in the HPLC system can be a problem, particularly when acetonitrile is used as the organic phase, owing to the poor solubility of buffer salts in high percent-organic solutions. Methanol usually is less of a problem than acetonitrile. Although a buffer may be soluble in a bulk solution, for example in 80% acetonitrile, the mixing characteristics of HPLC systems can cause buffer to be mixed directly with 100% acetonitrile under conditions that will precipitate the buffer. Precipitated buffers are difficult to remove and can foul check valves and column frits. A four-fold approach to check for and avoid such problems usually is successful. First, add the buffer phase drop-wise to the organic phase in a test tube.

If any cloudiness is observed when the buffer contacts the organic, it is likely to happen in the HPLC system as well. Second, keep the buffer concentration low (e.g. ≤25 mM). Third, premixing the buffer and organic may be helpful. For example, mix 5% buffer in the B reservoir and 5% B-solvent in the A-reservoir. Finally, avoid 100% acetonitrile gradients. Often running a 5–80% acetonitrile–buffer gradient will give the desired gradient conditions without the potential for buffer precipitation as the gradient nears 100% acetonitrile.

1 INTRODUCTION

The concept of what is now called IC was first described by Small, Stevens, and Bauman in 1975. They described a chromatographic separation/detection strategy that is applied to the determination of inorganic and organic analyte anions and cations. The method consists of three main components: (1) a low-capacity ion-exchange column, where the separation occurs; (2) a suppressor system, which reduces conductivity due to the mobile phase electrolyte; and (3) a conductivity detector, which is used to detect the analyte ions. Anionic analytes are separated on an anion-exchange column and analyte cations are separated on a cation-exchange column. IC, which is routinely applied in water, environmental, health, and food analysis, is a rapid, sensitive, and accurate method for the trace determination of complex mixtures of analyte ions, particularly analyte anions, where no other method offers similar advantages and scope of application.

Today, the term IC defines a broader group of methodologies applicable to the separation of analyte ions and now also defines the following strategies. Nonsuppressed IC of analyte anions and cations is possible. In addition, analyte ions can be separated with an ion interaction reagent (ion pair reagent) as a mobile phase additive and a reversed stationary phase column rather than an ion-exchange column; this is often called ion interaction chromatography (IIC). Ion exclusion chromatography (IEC), which is a separation of weakly dissociated acid and base analytes on an anion exchanger, is also an important methodology within the field of IC.

1 INTRODUCTION

The concept of what is now called IC was first described by Small, Stevens, and Bauman in 1975. They described a chromatographic separation/detection strategy that is applied to the determination of inorganic and organic analyte anions and cations. The methodology consists of three main components: (1) a low-capacity ion-exchange column, where the separation occurs; (2) a suppressor system, which reduces conductivity due to the mobile phase electrolyte; and (3) a conductivity detector, which is used to detect the analyte ions. Anionic analytes are separated on an anion-exchange column and analyte cations are separated on a cation-exchange column. IC, which is routinely applied in water, environmental, health, and food analysis, is a rapid, sensitive, and accurate method for the trace determination of complex mixtures of analyte ions, particularly analyte anions, where no other method offers similar advantages and scope of application.

Today, the term IC defines a broader group of methodologies applicable to the separation of analyte ions and now also defines the following strategies. Nonsuppressed IC of analyte anions and cations is possible. In addition, analyte ions can be separated with an ion interaction reagent (ion pair reagent) as a mobile phase additive and a reversed stationary phase column rather than an ion-exchange column; this is often called ion interaction chromatography (IIC). Ion exclusion chromatography (IEC), which is a separation of weakly dissociated acid and base analytes on an anion exchanger, is also an important methodology within the field of IC.
Ca\textsuperscript{2+}, were completely separated on anion and cation exchangers, respectively, in 10–15 min at analyte levels as low as 1 ppm depending on the analyte and the mixture. For example, Na\textsuperscript{+} and K\textsuperscript{+} were readily determined in urine, blood serum, and fruit juices while anions were determined in treated and untreated water. Often the samples could be handled in a dilute and shoot strategy, that is, the sample is diluted and an aliquot of this solution is introduced into the column for the separation. Thus, the sample matrix did not have to be removed from the sample prior to analysis. It was also possible through pH control to separate simple organic amines as cations and organic acids as anions. For the first time mixtures of simple inorganic and organic anions and cations could be separated and determined quickly, often in minutes, and at trace to ultratrace levels often in parts per million to sub-parts per million quantities.

Small et al.\textsuperscript{(1)} referred to the methodology as “Conductive Chromatography”. However, as the significance of this work became recognized and was commercially developed this separation methodology quickly became known as IC. The introduction and subsequent development of IC is of tremendous practical consequence in quantitative analytical chemistry and applications of liquid column chromatography. This is illustrated by Figure 1(a) and 1(b) where ion chromatograms for the separation of test samples of inorganic anions and cations respectively, are listed using current state-of-the-art ion chromatographic mobile-phase conditions, columns, and instrumentation. The chromatography is reproducible and peak area and peak height are proportional to analyte concentration; thus, unknown analysis through calibration is accurate, precise, and sensitive. Furthermore, analysis time is remarkably short. No other analytical method offers such a rapid, accurate, and yet relatively simple procedure for the trace analysis of these kinds of analyte ions.

IC was quickly recognized as one of the foremost methodologies for the determination of simple inorganic and organic analyte ions. It quickly became a routine analytical method that was applied to the determination of water quality and analysis of environmental, biological fluid, food, and industrial samples and related products, by-products, and materials. IC can be performed manually at the bench with individual samples, it can be automated, and it can be used in on-line process monitoring. IC measurements in the field are also possible. Many IC procedures are approved by regulatory agencies, for example the United States Environmental Protection Agency (USEPA), and are invaluable in industrial, health, food, electronic, and environmental analytical laboratories. At present IC procedures often serve as the standard to which other newly developed analytical methodology is compared particularly when considering

the analysis of simple inorganic and organic anions and cations.

The scope of IC as demonstrated by Small et al.\(^{(1)}\) has broadened and the modern use of the terminology in chromatography means more than the ion-exchange separation of analyte ions and their detection by conduc-
tance following suppression of mobile-phase electrolyte. The following sections, while focusing on suppressed IC and its advances, also briefly introduces other advances in IC, namely improvements in ion-exchange column technology, detection, and ion interaction reagents and advances in nonsuppressed IC, IIC and IEC. A more detailed discussion of the principles and applications of IC, nonsuppressed IC, IIC, and IEC is available in several excellent reference books.\(^{(2-5)}\)

Clearly, successful application of IC and related strategies to provide solutions to important separation problems rests on four major factors. For a particular separation problem these are: (1) selection of the correct ion-exchange column based on an understanding of the underlying properties of the exchanger, (2) being aware of the scope of the eluting conditions relative to the analyte mixture and the problem at hand, (3) carrying out a systematic manipulation of the first two factors to establish the required resolution of the analyte ions within the column and to obtain detector compatibility at the desired DL, and (4) handling of the chromatographic data to solve the problem at hand.

## 2 BASIC PRINCIPLES OF ION EXCHANGE

### 2.1 Ion-exchange Equilibrium

To understand why analyte ion separations occur in IC it is necessary to understand ion-exchange chromatography or the separation of analyte ions on a column containing an ion exchanger. A typical ion exchanger is an insoluble solid substance containing fixed charge centers (ionogenic groups) and exchangeable counterions of opposite charge associated with the ionogenic groups. These counterions can be exchanged for a stoichiometrically equivalent amount of other ions of the same sign when the ion exchanger is in contact with an electrolyte solution. Cation exchangers exchange cations and anion exchangers exchange anions.

The cation-exchange process, where H\(^+\) and Na\(^+\) are competing for the exchange site by electrostatic attraction, can be represented by

\[
R^-H^+_\text{(s)} + Na^+_{\text{(aq)}} = R^-Na^+_\text{(s)} + H^+_{\text{(aq)}}
\]  

(1)

In Equation (1) \(R^-\) is the solid insoluble exchanger containing a negatively charged ionogenic group, (s) is the solid form, and (aq) is the aqueous form. For anion exchange, where OH\(^-\) and Cl\(^-\) are competing for the anion-exchange site by electrostatic attraction, the process is represented by Equation (2)

\[
R^+OH^-_{\text{(s)}} + Cl^-_{\text{(aq)}} = R^+Cl^-_{\text{(s)}} + OH^-_{\text{(aq)}}
\]  

(2)

In this case \(R^+\) is the solid insoluble exchanger containing a positively charged ionogenic group. Many naturally occurring and synthetic materials are capable of exhibiting ion-exchange properties but those that are of the most interest in IC are ion exchangers that are specially synthesized for IC applications.

### 2.2 Properties of Ion Exchangers

#### 2.2.1 Ion-exchange Selectivity

The equilibrium constants, \(K\), for reactions (Equations 1 and 2), which are given by expressions (Equations 3 and 4), respectively, are selectivity constants because each specifies the relative preference of the ion exchanger for one ion over the other.

\[
K_{\text{Na}}^\text{H} = \frac{[R^-Na^+][H^+]_{\text{aq}}}{[R^-H^+][Na^+]_{\text{aq}}}
\]  

(3)

\[
K_{\text{OH}}^\text{Cl} = \frac{[R^+Cl^-][OH^-]_{\text{aq}}}{[R^+OH^-][Cl^-]_{\text{aq}}}
\]  

(4)

By designating one ion as a standard, a selectivity scale can be established for other ions of similar charge relative to the standard ion. For cation exchange H\(^+\) is the standard while for anion exchange the standard is usually OH\(^-\) or Cl\(^-\). Table 1 lists cation- and anion-exchange selectivities for a typical strong acid cation and strong base anion exchanger, respectively, where the exchanger matrix is polymer based. It should be noted that selectivity will be influenced not only by the ion exchanger ionogenic group but also by the exchanger matrix to which the ionogenic

group is bound. In general, when all other factors are equal ion exchangers exhibit higher binding (increased selectivities) for multivalent ions, for ions with decreased hydrated radius, and for ions with increased polarizability.

2.2.2 Reversibility
Equations (1) and (2) are equilibrium reactions that are stoichiometric and reversible. Typically, equilibrium is reached quickly. Consider Equation (1) where Na⁺ and H⁺ are competing for the exchanger anionic site. If the exchanger is placed in an aqueous environment and H⁺ and Na⁺ (and a suitable anion) are present in equal molar quantities, equilibrium is reached according to the selectivity given by the equilibrium constant in Equation (3). On the other hand if the cation exchanger in the H⁺ form is put in a column and a Na⁺ solution (for example aqueous NaCl) is continuously passed through the column, H⁺ will be continuously removed from the column and will be replaced by the Na⁺ until all the H⁺ has been replaced. When all the H⁺ is removed the Na⁺ concentration entering the column will equal the Na⁺ leaving the column. If the Na⁺ solution is washed out of the column and an aqueous HCl solution is now passed through the column, the exchanger will be converted back to the H⁺ form. Thus, Equation (1) can be driven in either direction by either a batch or column operation. Furthermore, the equilibrium can be driven by a cation that has a lower selectivity than the other by using the cation at a higher concentration or by continued passage of the cation solution through the column. This is possible because of mass action.

Binding is quantitative and stoichiometric. Selectivity also determines the order of ion removal from the exchanger and corresponds to the ion elution order if several different analyte ions are present. Since the exchange process usually occurs rapidly, column experiments can be carried out efficiently and reproducibly.

2.2.3 Rate of Ion Exchange
Equilibrium is reached rapidly because rates of exchange are usually high. Exchange rates are controlled by diffusion within the exchanger particle, if ionogenic groups within the particle are accessible, and by film diffusion at the exchanger particle surface. Physical properties of the exchanger (see section 2.2.6 in the following) and the type of ionogenic group will influence exchange rates. While ion exchangers are usually high, strong base ionogenic groups are low. Exchange rates are controlled by film diffusion within the exchanger particle, if ionogenic groups within the particle are accessible, and by film diffusion at the exchanger particle surface. Physical properties of the exchanger (see section 2.2.6 in the following) and the type of ionogenic group will influence exchange rates.

When an ion exchanger is used in a column to bring about analyte separation due to differences in analyte exchange selectivity, only a small portion of the available exchange capacity should be employed to prevent a column analyte mass overload. Exchange capacity is also sensitive to ion-exchanger physical properties (see section 2.2.6 in the following) because these properties influence the accessibility of the exchange sites.

2.2.5 Ionogenic Group
Ionogenic groups or ion-exchange sites are classified as being either strong or weak acid or base groups. Strong acid and base groups are highly dissociated and the exchangers containing these groups are like insoluble strong electrolytes. These groups are −SO₃⁻H⁺ and −NR₃⁺OH⁻ and exchange cations and anions, respectively. Common weak acid ionogenic groups are −CO₂H, −PO₃H₂, aromatic −OH, and aromatic −SH while weak base ionogenic groups are −NH₂, −NHR, and −NR₃. These are like insoluble weak electrolytes and their ability to participate in ion exchange as cation and anion exchangers, respectively, depends on dissociation of the group and therefore on their ionization constant and the pH of the environment. The ionogenic groups can be chemically bound to an organic polymer matrix or chemically bound to silica or other oxides.

2.2.6 Physical Properties
Ion exchangers developed for IC applications must satisfy the physical properties demanded by modern liquid chromatography (LC) in addition to providing the desired ion-exchange properties. The exchangers must be available as small, physically strong, uniform size, spherical microparticles that can be reproducibly packed into an efficient column.

Ion exchangers based on an organic polymeric matrix will expand and contract when placed in water or a polar solvent. A highly polar medium favors swelling while a less polar environment favors contraction. Both the type of solvent and the presence of an electrolyte and its concentration influence swelling and contraction. Increased cross-linking in the organic polymer matrix increases physical strength, reduces swelling and solubility, and affects the accessibility of the exchanger sites within the organic polymer and therefore the available exchange capacity. Bead fracture can occur because of rapid swelling or contraction of the ion exchanger. Higher cross-linking will reduce bead fracture and increase particle stability. Rapid swelling and contraction can cause discontinuity in the column packing since these processes will occur in the column when solvent and/or electrolyte concentration of the mobile phase are changed abruptly.
Cross-linking, swelling/contraction, and related properties are more specific to organic polymeric ion exchangers and are generally of less concern with pellicular, latex, or silica-based ion exchangers.

The polymerization strategy used to prepare the polymeric-based ion exchanger will also influence its properties. Polymeric ion exchangers can be prepared that are either gel-like or macroporous. The former have low surface areas and are not truly porous. Their porous-like property is obtained only when the polymer is swollen. In contrast the macroporous polymer has a high surface area and has high porosity. This is because it is a spherical particle that is made up of many ultramicrogel particles joined together. Its porosity is therefore not dependent on swelling of the bead but more so on the space that is present between the attached microgel beads.

The organic polymeric, pellicular, latex, and silica-based ion exchangers are commercially available as spherical particles of uniform microparticle size. Bulk lots of the exchangers can be purchased to pack columns in the laboratory. However, commercially packed columns are used most often because they are available commercially and provide excellent column efficiency and reproducibility.

2.2.7 Stability

A useful ion exchanger in IC must withstand the usual rigors of modern LC and mobile phases routinely used in IC. Bead fracture, swelling/contraction, and reactivity towards eluents can cause serious limitations in IC applications. Organic polymeric, pellicular, and latex-based ion exchangers are stable throughout the pH range of 1 to 14. Silica-based ion exchangers, in contrast, are stable within the range of pH 2 to 9. The ionogenic groups are generally stable; however, the \(-R_1N^+X^-\) ionogenic group is the least stable particularly when \(X^-\) is OH\(^-\) and when the exchanger is dry.

2.2.8 Ion-exchanger Matrix

Ion exchangers for IC are organic polymeric, latex, pellicular, or silica-based and the nature of the matrix can have a strong influence on the chromatographic result. Syntheses of these four types of exchangers are briefly described in the next section.

For an ion exchanger with an organic polymeric matrix its composition, cross-linking, and porous or gel-like properties influence the accessibility of the ionogenic groups, the rate of exchange, and compatibility with mixed and/or nonaqueous solvents. The matrix can also interact with nonionic materials, which may be present in the analyte sample, and over time can alter the column performance. Organic analytic ions that are lipophilic may also interact with the matrix through hydrophobic interactions in addition to ion exchange. Pellicular ion exchangers with a polymeric core can exhibit similar properties but to a much lesser degree.

Analyte hydrophobic interactions are not encountered with pellicular ion exchangers with a silica core or silica bonded-phase ion exchangers. However, these exchangers have a limited useful pH range and can have residual silanol (\(-SiOH\)) sites. These sites are weakly acidic and will exhibit cation-exchange properties. The latex ion exchangers typically do not exhibit hydrophobic matrix-retention interactions but they can exhibit both anion and cation exchange depending on their synthesis. A more detailed discussion of the properties of ion exchangers is available in several excellent reference books.\(^{6,7}\)

3 ION EXCHANGERS IN ION CHROMATOGRAPHY

The major types of anion and cation exchangers used in IC are organic polymeric-based, latex-based, and silica bonded-phase exchangers. These exchangers for IC applications are low in exchange capacity, typically less than 200 \(\mu\)eq g\(^{-1}\), and most often have ionogenic sites on the outer particle surface rather than on the interior of the particle.

3.1 Polymeric Ion Exchangers

Most organic polymeric-type ion exchangers are derived from polystyrene–divinylbenzene (PSDVB) copolymers. Other polymer types used are polyvinyl and polymethacrylate polymers.

PSDVB is prepared by reaction of styrene (1) and divinylbenzene (2) using the appropriate solvent, catalyst, and reaction conditions according to Scheme 1.

The amount of divinylbenzene used in the synthesis determines the amount of cross-linking in the copolymer and influences the exchanger properties as outlined earlier. The anion exchanger, often referred to as a strong base anion exchanger, is prepared by chemically bonding a quaternary ammonium group to the PSDVB copolymer by chloromethylation of the copolymer followed by reaction with a tertiary amine. This is shown in Scheme 2, where the PSDVB copolymer is represented by the benzene ring. While the \(R\) groups can be varied, they typically are methyl groups and the anion exchanger is frequently supplied in the \(Cl^-\) form rather than in the \(OH^-\) form because the latter is less stable particularly when dry.

The cation exchanger, often referred to as a strong acid cation exchanger, is prepared by a sulfonation procedure.
In this case a $-\text{SO}_3^+\text{H}^+$ ionogenic group is bound to the PSDVB copolymer as shown in Scheme 3, where the benzene ring represents the PSDVB copolymer. Usually, commercially available columns packed with the strong acid cation exchanger are supplied in the H$^+$ or Na$^+$ form. Both are equally stable forms. For both the PSDVB strong acid and base cation and anion exchangers for IC the ionogenic groups are primarily located on the surface of the spherical copolymer beads. For this reason ion-exchange capacity is low but mass transfer for exchange is more favorable. High-capacity ion exchangers, where exchange groups are located on the surface and within the bead, are commercially available. These are usually not used in IC but are useful for IEC. The surface-covered exchangers are preferred because of better exchange kinetics and a more rapid attainment of equilibrium. Other kinds of ionogenic groups exhibiting ion-exchange properties have been prepared but are not necessarily available with an ion-exchange capacity suitable for IC. Several of these are listed in Table 2. It is important to note that all of these have weak acid or base properties and dissociation of the groups, and therefore the ion-exchange properties are pH dependent. The strong acid and base ion exchangers in contrast are highly dissociated like strong insoluble, electrolytes and will exhibit ion-exchange properties throughout the pH range.

Ion exchangers that contain the PSDVB matrix will swell in polar solvents and in the presence of electrolyte. Sharp changes in their concentrations can cause rapid and excessive swelling or contracting and can lead to bead fracture. The PSDVB-type exchangers that are of the gel type owing to the polymerization procedure, will typically contain 2–16% divinylbenzene as the cross-linking agent to inhibit swelling/contracting. This gel-type PSDVB, however, is not truly porous-like as a sponge and its porous-like property results from expansion (or contraction) between the copolymer chains. The gel-type ion exchanger, thus, will have an apparent porosity and surface area which are typically very low even when swollen, that is, dependent on the extent of the bead swelling.

A macroporous (also called porous, isoporous, or macroreticular) PSDVB copolymeric-based ion exchanger can be made via modifications in the polymerization strategy. The copolymer for the ion exchanger is still derived from styrene and divinylbenzene, (see Scheme 1) is highly cross-linked ($\geq 16\%$), and yields a network of submicrometer gel beads joined together to form a larger, spherical, single bead. The high porosity and surface area, which are much less dependent on bead swelling/contraction, are more permanent because the interstitial spaces between the microgel beads are largely responsible for the porosity. Pore diameters and surface area can exceed 10 nm and $100\text{m}^2\text{g}^{-1}$, respectively. The gel-type-derived ion exchanger, in contrast, has only a fraction of this porosity and surface area depending on swelling/contraction. The macroporous-based ion exchangers are physically strong and have favorable ion-exchange rates and mass transfer provided exchange capacity is on the surface particularly when mixed solvents are used. Macroporous ion exchangers with high ion-exchange capacities can be made but the macroporous ion exchangers usually used in IC are low capacity.

$^a$ Commercially available for IC.
3.2 Latex-based Ion Exchangers

Latex-based anion and cation exchangers for IC applications are commercially available. These are pellicular in nature, that is, the ionogenic groups are primarily located on the outer surface of the particle.\(^{(6)}\) For the anion exchanger a surface-sulfonated PSDVB particle is the matrix and this is covered by aminated latex microparticles. Since the sulfonated groups are in excess, it functions as a cation exchanger. This type of latex-based cation exchanger, however, suffers from poor reproducibility and chemical stability. A more reliable latex-based cation exchanger is prepared by taking a sulfonated PSDVB particle, coating it with aminated latex microparticles as an inner layer and coating this layer with a layer of sulfonated latex microparticles. A typical structure for the cation latex-based ion exchanger is shown in Figure 2(a). The quaternary ammonium groups are in large excess compared to the sulfonic acid groups and the net effect is that anion exchange occurs at the bead surface.

The cation latex-based ion exchangers can be prepared in a similar fashion except that the PSDVB copolymeric surface is first aminated and this is subsequently covered with sulfonated latex microparticles. Since the sulfonated groups are in excess, it functions as a cation exchanger. This type of latex-based cation exchanger, however, suffers from poor reproducibility and chemical stability. A more reliable latex-based cation exchanger is prepared by taking a sulfonated PSDVB particle, coating it with aminated latex microparticles as an inner layer and coating this layer with a layer of sulfonated latex microparticles. A typical structure for the cation latex-based ion exchanger is shown in Figure 2(b). In this case the sulfonated groups on the outer layer due to the sulfonated latex microparticles are in excess and cation exchange occurs at this sulfonated surface.

Properties of the two exchangers can be altered by changes in the matrix and the ratio of the aminated or the sulfonated latex to the pellicular sulfonated or aminated groups. In general, cation and anion retention order is the same for both the PSDVB and latex-based strong-acid and base cation and anion exchangers. However, selectivity differences for the latex-based exchangers can be modified, but usually not reversed. The cross-linking in the PSDVB core can be changed, the particle size of the latex particles can be changed, and the number of charged sites on the core versus the number in the latex microparticles can be altered. Consequently, resolution of anions or cations in IC can be improved by modification of one or more of these properties. A different particle core material can also be used. For example, acrylate-based latex anion exchangers have been prepared and are commercially available. These are often preferred for the separation of anions of high anion-exchange selectivity, such as phosphate and sulfate, because their retention on this anion exchanger is much less. Because of these modifications several different latex anion and cation exchangers have been developed for the separation of specific kinds of mixtures and are commercially available from Dionex Corporation. Furthermore, because both aminated and sulfonated groups are present in the latex-based exchangers, these exchangers are capable of exhibiting both anion- and cation-exchange properties simultaneously even though one group is in excess over the other.\(^{(9)}\)

3.3 Silica-based Ion Exchangers

Introduction of the bonded stationary phase, where the stationary phase is chemically bonded to silica (also now to alumina and zirconia) to HPLC was a milestone event in the development of HPLC. While the major thrust in the initial studies with bonded phases focused on the development of reversed stationary phases and to a lesser extent normal stationary phases, research also emerged on the synthesis of bonded-phase ion exchangers. Those of interest in IC are low in exchange capacity and are usually prepared by silanization chemistry.

Typically, silica-based ion exchangers are prepared by silanization of the silica silanol (Si–OH) sites with chlorosilane reagents that contain the ionogenic group, or groups that will undergo additional reactions to introduce the ionogenic groups. Strong acid (–SO\(_3\)H\(^+\)) and strong base (–NR\(_3\)+) silica-based cation and anion exchangers are commercially available as are weak acid (–CO\(_2\)H) and base (–NH\(_2\)) ion exchangers. The commercially available silica-based bonded-phase ion exchangers typically have high surface areas (>200 m\(^2\) g\(^{-1}\)), are physically strong, do not swell/contract as solvent or electrolyte is changed, and provide high column efficiencies. However, they have a limited pH range of about pH 2 to 9 because of reactivity of the silica and the bonded group towards acid and base. They are commercially available as packed columns of uniform spherical microparticles of 3, 5, or 10 \(\mu\)m. Exchange capacities can be varied in the synthesis and in general those that are

![Figure 2 Latex-based ion exchangers, (a) anion exchanger, (b) cation exchanger.](image-url)
commercially available and used in IC are low in capacity although their capacity is greater than the typical IC polymer and latex-based ion exchangers.

A pellicular-type silica-based ion exchanger is formed by depositing the ion exchanger matrix as a thin layer onto the surface of an inert core particle which is spherical, microparticle, and uniform in size. The ionogenic group is then attached to the matrix. Strong acid and base and weak acid and base ion exchangers have been made this way and several are commercially available. Typical core materials are a glass bead or a nonporous silica bead while the matrix layer is typically PSDVB or another polymer that provides reaction centers for the bonding of the ionogenic groups. One important weak acid pellicular-type cation exchanger with a silica core is an exchanger that has a poly(butadiene–maleic acid) copolymer covering and weak acid carboxy (−CO₂H) ionogenic groups. This type of cation exchanger is particularly useful for the simultaneous separation of alkali metals and alkaline earths (see Figure 3) with short analysis times and with a single eluent. This kind of separation is not easily accomplished with −SO₃H⁺ polymer or latex-based cation exchangers.

![Image](image_url)

### 3.4 Other Exchangers Used in Ion Chromatography

Other stationary phases used in IC are chelating ion exchangers and certain inorganic oxides and salts. Most chelating exchangers will contain acidic or basic groups that can participate in ion exchange in addition to the chelating group. The major interaction, however, is coordination between the analyte, usually a cation analyte, and the coordination center of the chelating exchanger. Chelating exchangers can be highly selective and this property can be predicted from known stability constants for complex formation between the analyte cation and the ligand in solution. Chelating ion exchangers are used more often for isolating and concentrating trace levels of cations rather than for the resolution of complex mixtures of cations. The high selectivity and stability of complex formation favors the former while slow exchange kinetics is a major handicap to the latter application. Few chelating ion exchangers for IC are commercially available.

Inorganic oxides and salts can participate in cation and/or anion exchange because they also exhibit weak acid and base properties. The ion-exchange property and ion-exchange capacity are therefore pH dependent. The exchange behavior of oxides also depends on many other environmental factors including buffer and inert electrolyte components and concentration in the mobile phase, pretreatment, heat treatment, ageing, method of preparation, crystallinity, and surface area. Furthermore, few are available as uniform spherical microparticles that meet high column-efficiency requirements. Notable exceptions are alumina, silica, and zirconia. Their uniqueness in IC applications comes from the fact that inorganic analyte anion and cation ion-exchange selectivities, and consequently analyte elution order, on the oxides and salts are often different to those obtained with the −SO₃H⁺ and −NR₃⁺ X⁻ cation and anion exchangers, respectively. Unfortunately, the stability of the inorganic oxides and salts as exchangers in an aqueous environment is not the same as the stability and reproducibility offered by the polymeric and latex-based cation exchangers.

### 4 ION EXCHANGE SEPARATIONS

Ion exchange is the main separation strategy that is used to separate ionic analytes. The chromatographic system consists of a separation or analytical column packed with an anion exchanger to separate anions or a cation exchanger to separate cations. The mobile phase will contain an electrolyte that provides a competing ion (anion for anion exchange and cation for cation exchange) of suitable ion-exchange selectivity (see Table 1) and concentration. When the mixture of analyte ions is introduced and carried into the column by
the mobile phase, the analyte ions are electrostatically attracted to the ionogenic groups. They are subsequently released to the mobile phase by competitive electrostatic attraction between the competing ions provided by the mobile-phase electrolyte and the analyte ions. Separation occurs because the analytes migrate through the column at different rates because of differences in their ion-exchange selectivities. The separation is completed by detection of the analyte ions as they emerge from the column. Absorption, fluorescence, and electrochemical detection are common detection modes in HPLC, but these detection strategies have limitations in direct detection of the ion-exchange separation of simple inorganic and organic anions and cations because most of these analytes are detector inactive. Conductivity, however, should be a universal detector for ionic analytes as most would have high ionic equivalent conductances. Unfortunately, conductivity detection in ordinary ion-exchange separations is not very sensitive because the analyte ion conductivity signal-to-noise ratio (S/N) is very small. In a typical ion-exchange separation the mobile phase itself is highly conducting because of the electrolyte required in the mobile phase.

Consider the case where an analyte mixture of Cl\(^-\), Br\(^-\), and I\(^-\) are being separated on an anion-exchange separator column capable of delivering high column efficiency. An aqueous NaOH mobile phase of suitable concentration is used and detection is by conductivity. The chromatographic set-up is shown in Figure 4. The sample is introduced as a small aqueous aliquot of sodium salts and the NaOH mobile phase carries the sample into the anion-exchange column. Anion exchange occurs according to the exchange equilibrium listed in Equation (5)

\[
S^-NR_3^+OH^- + X^- = S^-NR_3X^- + OH^-
\]  

where S is the exchanger matrix and X\(^-\) is Cl\(^-\), Br\(^-\), and I\(^-\). Because of the anion ion-exchange selectivities (see Table 1) and the electrostatic competition between OH\(^-\) and the analyte anions towards the anion-exchange site, Cl\(^-\) travels the fastest and I\(^-\) the slowest and resolution starts to occur in the column as shown in Figure 4. When the analytes as the Na\(^+\) salts emerge from the column as separated chromatographic zones they do so in the presence of the NaOH mobile phase. They subsequently pass into the conductivity detector where conductance of the flowing stream is determined. Because the conductivity for the NaOH is very high, the conductance signal caused by the presence of the three analytes is very small, S/N for the analyte anions is not favorable, and detection is poor. This is illustrated in the chromatogram in Figure 4, where the peaks correspond to the Na\(^+\) salts of the analyte anions. If the NaOH was absent in the background, conductivity for the background would be very low and the three analyte signals would be very high. Thus, S/N would be very favorable and detection would be very sensitive. This major problem was solved by the suppressed IC strategy developed by Small et al.\(^{(1)}\)

5 SUPPRESSED ION CHROMATOGRAPHY

5.1 Suppression by an Ion Exchanger

In the suppressed IC strategy developed by Small et al.\(^{(1)}\) a mixture of analyte anions or cations are separated by high-performance ion exchange and the analytes are detected by conductivity. In their strategy the key to a favorable S/N and sensitive detection is the removal or reduction of the mobile-phase background conductance due to the mobile-phase electrolyte. To separate analyte anions a low-capacity strong base anion-exchange column (separator or analytical column) is used for the separation and a high-capacity strong acid cation-exchange column connected in series serves as the suppressor column. For the separation of analyte cations the system is reversed or the analytical column is a strong acid low-capacity cation exchanger and the suppressor column is a high-capacity strong base anion exchanger. The basic instrumental set-up for anion and cation suppressed IC is shown in Figure 5(a) and (b), respectively.

Consider the nonsuppressed Cl\(^-\), Br\(^-\), and I\(^-\) anion-exchange separation illustrated in Figure 4. When this separation is carried out by an IC suppression strategy the effluent from the separator column is passed first

![Figure 4 Separation of halides on an anion exchanger without postcolumn suppression.](image-url)
and then through the conductivity detector. In the
exchanger charged in the H\textsuperscript{+} form as shown in Figure 5(a) and then through the conductivity detector. In the

Conductivity detector
\[ \text{Waste} \]

Figure 5 Separation of anions (a) and cations (b) with post-
column suppression. P stands for a polymeric matrix of the
exchanger.

into the suppression column of a strong acid cation
exchanger charged in the H\textsuperscript{+} form as shown in Figure 5(a) and then through the conductivity detector. In the

suppression column NaOH, NaCl, NaBr, and NaI are
converted to HOH, HCl, HBr, and HI, respectively, according to the exchange equilibrium summarized by Equation (6).

\[
S-\text{SO}_3^{-}\text{H}^{+} + \text{Na}^{+} = S-\text{SO}_3^{-}\text{Na}^{+} + \text{H}^{+} \quad (6)
\]

Thus, when the effluent from the suppressor column
passes through the conductivity detector the background
is water and the analytes are the corresponding acids. Conductivity detection is therefore very sensitive because of the absence of the background conductance, S/N is high, and DLs are significantly reduced compared to the absence of the suppression column. The conductivity
signals are also enhanced because the analytes are present
as the acids rather than the Na\textsuperscript{+} salts in the detection step. The ionic equivalent conductance for H\textsuperscript{+} is about 7 times
that of Na\textsuperscript{+} which enhances the conductivity signal. This
internal signal amplification is another advantage of the
suppression system.

For the separation of analyte cations, for example the
separation of Li\textsuperscript{+}, Na\textsuperscript{+}, and K\textsuperscript{+} as Cl\textsuperscript{−} salts (see Figure 5b), a strong acid, low-capacity cation
exchanger is used for the separator column and a strong base, high-capacity anion exchanger in the OH\textsuperscript{−} form is used for the suppressor column. An HCl mobile phase is used for the separation of the cation analytes. The separation
occurs because of the differences in cation selectivities for
the three analyte cations (see Table 1) and competition between the cations and H\textsuperscript{+} for the cation-exchange sites. The exchange equilibria are summarized by Equation (7)

\[
S-\text{SO}_3^{-}\text{H}^{+} + \text{M}^{+} = S-\text{SO}_3^{-}\text{M}^{+} + \text{H}^{+} \quad (7)
\]

where M\textsuperscript{+} is Li\textsuperscript{+}, Na\textsuperscript{+}, and K\textsuperscript{+}. If the effluent from the separator column is passed directly into the conductivity
detector in Figure 5(b), the detector would detect LiCl,
NaCl, and KCl in that order on an HCl background. Conductance of the background is very high and conductance change due to the analytes would be small. However, if the effluent is passed into the suppression
ion-exchange column, which is a high-capacity strong base anion exchanger charged in the OH\textsuperscript{−} form, the HCl background electrolyte and the alkali metal chloride
analytes are converted to HOH and LiOH, NaOH, and KOH, respectively, as summarized by Equation (8)

\[
S-\text{NR}_3^{+}\text{OH}^{-} + \text{Cl}^{-} = S-\text{NR}_3^{+}\text{Cl}^{-} + \text{OH}^{-} \quad (8)
\]

Thus, detection of each analyte by the conductivity
detector is very sensitive because detection of the
analyte takes place in an electrolyte-free background.
Furthermore, the signal is enhanced because the analytes
are detected as the OH\textsuperscript{−}, which has a much higher ionic
equivalent conductance compared to Cl\textsuperscript{−}. 
This separation/detection strategy was quickly recognized as a superior method for the rapid, accurate, and sensitive separation and determination of simple inorganic and organic ionic analytes. Analysis times and DLs obtained by this strategy were not possible by other methods.

The mobile-phase electrolytes used in Figure 5(a) and (b) are strong acid and base electrolytes, respectively, and when suppression is employed background conductance due to the electrolyte is overcome. Both eluents are modestly weak in eluent strength, which can be increased only by an increase in the concentration electrolyte. If a stronger eluent is required, which would be needed for example to separate highly retained analyte anions, an electrolyte that provides an anion of higher selectivity must be used (see Table 1). This is possible with suppression by using salts of weak acids and bases for the mobile-phase electrolyte in anion and cation separations, respectively. In the suppression step these electrolytes are converted to weak acids and bases, respectively. Because the weak acids and bases are poorly dissociated ($K_a$ and $K_b$ are therefore an important variable) their contribution to background conductance is low, S/N is favorable, and conductivity detection is still sensitive.

The suppression strategy outlined in Figure 5(a) and (b) had several limitations. DLs, while being favorable, were still limited by the analyte peak broadening that occurs in the separator column and even more so in the suppression column. Reduction of the broadening and an increased resolution was subsequently addressed by the development of new ion exchangers specifically designed for the separator column for IC and new, more versatile mobile-phase/electrolyte mixtures to separate the analyte anions and cations. A second recognized problem was that the suppression column’s exchange capacity is exhausted in long-term operation, even though it has a high capacity. Therefore, continuous operation of this suppression IC system is not possible. The IC system would have to be shutdown either to replace or to regenerate the suppression column.

5.2 Membrane Suppression in Ion Chromatography

Development of a membrane suppressor was subsequently shown to overcome these two major problems of the high-capacity ion-exchange suppressor column, namely, peak broadening in the suppressor and inability to carry out continuous IC owing to the required suppressor regeneration. A schematic representation of an anion membrane suppressor that would be used to suppress background electrolyte in the separation of anions is shown in Figure 6(a). The central region where the eluent flows is microvolume in size and is sandwiched by two sulfonated cation-exchange membranes. A regeneration chamber is on opposite sides of the membranes and the entire device is enclosed in a small leakproof unit.

Consider the IC separation shown in Figure 5(a) except that the ion-exchange suppression column is replaced by an anion membrane suppressor. As the column effluent from the anion-exchange separator column passes through the microvolume eluent chamber of the membrane suppressor, Na$^+$ is replaced by H$^+$ at the membrane. Simultaneously, a H$_2$SO$_4$ solution is continuously passed through the regeneration chamber and the Na$^+$ is then replaced by H$^+$. Thus, the suppression is continuous, band broadening is minimal, and conductivity DLs are significantly lower compared with those of the ion-exchange column suppression which was used in Figure 5(a). A 1–10 ppm DL (lower is possible) is often routine depending on the injection volume, analyte anion, and the separation conditions.

A cation membrane suppressor is also available and its schematic representation is shown in Figure 6(b). It functions much like the anion membrane suppressor except that the membrane is a strong base cation-exchange membrane charged in the OH$^-$ form and the regeneration solution is usually an aqueous R$_2$N$^+$OH$^-$ solution.

The membrane suppressor has low internal volume and can be used continuously to reduce background conductance to almost negligible levels depending on the mobile-phase electrolyte and its concentration. It is efficient, rapid, reproducible, solvent resistant, and is compatible with gradient elution. Maintenance is low and only occasional cleaning is needed. The membrane suppressor is also readily adapted for on-line operation for automated IC in industrial applications.

The commercially available membrane suppressor has also undergone stages of improvement. The key improvements are the following. First the internal volume of the suppressor is now markedly reduced without sacrificing suppression properties and is currently referred to as a micromembrane suppressor (MMS). The MMS provides better DLs, better mass transfer across the membrane, and is better suited to smaller diameter analytical ion-exchange columns. A second key advance is the replacement of the suppressor membrane regeneration process by a continuous electrolytic regeneration process. This modification is illustrated in Figure 7. In this case electrolysis of water is used to generate H$^+$ at the anode which is used to regenerate the anion MMS continuously, while for the cation MMS, OH$^-$ produced at the cathode is used for the regeneration. The extra pump, the delivery system, and the H$_2$SO$_4$ solution are no longer required. Regeneration is simplified, continuous, more efficient (which also allows reduction in the internal volume of the suppressor), and is applicable to a wide range of mobile-phase electrolytes in both isocratic and gradient modes.
5.3 Other Suppression Strategies in Ion Chromatography

Other kinds of postcolumn suppression strategies have been described in the literature. However, none of these offer the sensitivity, simplicity, versatility in applications, and excellent reproducibility offered by a MMS. Nonmembrane suppression procedures include precipitation of the mobile-phase electrolyte but not the analyte in a suppressor ion-exchange column\(^{11}\) or chelation\(^{12}\) of the electrolyte in the suppression step. Another suppression procedure is to pump a slurry of small ion-exchange particles into the analytical column effluent following the separation and prior to conductivity.
Postcolumn suppression by an ion-exchange column can also be done effectively and efficiently. This configuration differs from the earlier ion-exchange suppressor unit described by Small et al. in the following way. This system, which is commercially available from Alltech Associates, Inc., includes two ion-exchange columns as the suppressor with either one of the two in operation at any given time. If anions are being separated the separator column is still an anion exchanger and the two suppression columns are high exchange capacity, small in size (14 mm × 7.5 mm), and low in internal volume. For cation-exchange separations the separator column is a cation exchanger and the two suppression columns are anion exchangers. The reactions describing the anion and cation separations and suppression are the same as described earlier. The system is continuous because when one suppressor column is being used the other is being regenerated and equilibrated simultaneously. When the first suppression column is exhausted, which is indicated by a color change of an indicator incorporated into the exchanger, a valve switches the separator column effluent to the second suppressor column and the first is regenerated and equilibrated while the second is used for suppression. The regeneration in this two-column suppressor strategy is also done by continuous electrolysis of water. Continuous separations are therefore possible. Also, the suppressor need not be large so that band broadening and reduction in S/N are avoided and DLs are low.

MMSs have applications other than mobile-phase electrolyte suppression in IC. For example, the suppressor can be applied to sample cleanup prior to IC analysis. Another practical application is to use the suppressor to remove NaOH (up to 48%) from a concentrated NaOH solution prior to trace IC anion analysis in the NaOH solution. The MMS can also be used to enhance detection of organic analytes that are separated on reversed-stationary-phase columns when employing a mobile phase of high ionic strength. When these analytes cannot be detected by absorbance or fluorescence, the mobile-phase ionic strength electrolyte can be converted to a weakly conducting species with the MMS. This allows the analytes to then be detected by conductivity with good sensitivity. For example, anionic surfactants are separated on reversed stationary phases with good resolution only if the mobile phase is at a high ionic strength. The mobile-phase ionic strength electrolyte, which is a salt of a weak acid, is suppressed by an MMS which allows a sensitive conductometric detection of the anionic surfactant.

6 ELUENTS FOR SUPPRESSED ION CHROMATOGRAPHY

Eluent strength is determined by the mobile-phase electrolyte concentration and the electrolyte anion for the IC separation of anions and electrolyte cation for the IC separation of cations. A higher concentration or an ion of higher ion-exchange selectivity yields a stronger eluent.

Table 3 lists several common electrolytes that are used in the suppressed IC separation of anions. Eluent strength, in general, will increase from top to bottom although differences may be small depending on the electrolyte mobile-phase concentration. The key factors to optimize are: the mobile-phase electrolyte anion, the electrolyte concentration, and selection of the anion exchanger. If an electrolyte containing a weak acid anion is used, S/N, and hence DL, will depend on dissociation of the weak acid that is formed in the suppression step.

The useful electrolyte cations for suppressed anolyte cation IC separations are few in number. If the suppression step involves OH⁻, hydroxide precipitation depending on the electrolyte cation can interfere in suppressor and conductivity-detector performance. Many cation analytes, particularly multivalent cations, have high, similar cation-exchange selectivities and require a strong eluting condition. Because of the similarity in selectivities resolution is often poor even with a strong eluent electrolyte. This problem can be overcome in some cases by using a carboxylate-type cation exchanger or

DAP, 2,3-Diaminopropionic acid.
more often by including a complexing agent in the mobile phase. Thus, formation constants for the complexes that form between the complexing agent and the multivalent cations will determine the cation elution order. Typical complexing agents used in the mobile phase in addition to an electrolyte are ethylenediaminetetraacetic acid (EDTA) and citrate, tartrate, 2-hydroxybutyrate, and pyridine-2,6-dicarboxylate salts.

Alkali metal, other univalent and alkaline earth cations can be separated with suppression using strong mineral acids, alkyl sulfonic acids, and protonated forms of organic bases such as aniline, ethylenediamine, phenylenediamine, and DAP as the mobile-phase electrolyte. The eluent strength of the latter three are also pH dependent since they are polyprotic acids.

The electrolysis of water, which is the basis for electrochemical regeneration of the MMS, offers other advantages in IC separations. This strategy can be used in IC separations not only to prepare a highly purified mobile phase but also to increase electrolyte concentration electrically in the mobile phase for a gradient application. For example, a carbonate-free NaOH mobile phase can be prepared via water electrolysis and used for IC anion separation.\(^{18,19}\) Removal of the carbonate significantly lowers the DL for the separated anions.

A new version of IC, called ion reflux, also employs water electrolysis in a unique way to generate the mobile phase.\(^{19,20}\) Analytes are still separated by ion exchange and an electrolyte solution is still the eluent, but it is pure water that is pumped into the system. In ion reflux the electrolyte solution is generated in situ via electrolysis and either analyte anions or cations can be separated.

Figure 8 illustrates an ion-reflux unit for the IC separation of analyte anions. The unit is composed of a source of pure water, a pump, a sample injector, an anion-exchange separator column where the separation of the analyte anions takes place after the sample is injected into the ion-reflux unit, and a generator system where the eluent is formed. This generator system contains two cation exchangers, one is charged in the K\(^+\) form and is placed at the top while the bottom one is charged in the H\(^+\) form as shown in Figure 8. The cathode is in a cathode chamber and is separated from the K\(^+\) cation exchanger by a cation-exchange membrane (shown as the black region in Figure 8). Cations will pass through the membrane but anions do not owing to Donnan exclusion. When the potential is applied and pure water is flowing through the unit, electrolysis of the water will occur at the electrodes with OH\(^-\) as KOH (now the eluent electrolyte) forming at the cathode and H\(^+\) at the anode. The H\(^+\) produced at the anode helps to move the K\(^+\) through the cation-exchange membrane to form the KOH eluent. However, a steady state occurs in the generator because the eluent KOH and the separated analyte anions, after passing through the anion separator column, eventually reach the K\(^+\)/H\(^+\) cation-exchanger boundary of the generator part of the unit. At this point the KOH comes into contact with the H\(^+\)-form cation exchanger and is converted to HOH and the K\(^+\)-form cation exchanger. Thus, this is both the suppression step and a recharging of the K\(^+\) cation exchanger. In addition the analyte anions are converted into the acids which eventually pass through the conductivity detector. Since OH\(^-\) and H\(^+\) are produced in equivalent amounts during the electrolysis, the K\(^+\)/H\(^+\) boundary remains fixed when the steady state is established since K\(^+\) or H\(^+\) are not lost in the operation assuming the sample anions are introduced as the acids. Thus, ion reflux is water in and water plus the separated analyte anions out.

The elution process can be either isocratic or gradient, even though pure water is pumped into the unit. When the current is held constant, a fixed known eluent concentration is generated and the elution is isocratic. If the current is gradually increased in a...
known, reproducible manner, then a known, reproducible concentration gradient in OH⁻ as KOH is produced.

For the separation of cations in an ion-reflux unit the separating column is a cation exchanger and the other two exchangers in the generator part of the ion reflux unit are anion exchangers. The top anion exchanger is charged in either the Cl⁻ or CH₃SO₃⁻ form and is separated from the electrode by an anion-exchange membrane while the exchanger at the bottom is charged in the OH⁻ form.²⁰

### 7 NONSUPPRESSED ION CHROMATOGRAPHY

In nonsuppressed IC, analyte anions are separated usually on a strong base-type anion exchanger, and analyte cations on a strong acid-type cation exchanger. A typical IC set-up for nonsuppressed separation of anions, for example, is similar to that shown in Figure 4. If conductivity detection is used no attempt is made to reduce background conductivity by removal of the background electrolyte. The influence of background conductance on S/N and therefore DL is overcome by altering other factors in the ion-exchange process.

Fritz et al.²¹,²² exploited two features of ion exchange to improve conductivity detection in the absence of suppression. First, an ion exchanger was used that is very low in ion-exchange capacity but still capable of providing a high efficiency separation. Typically, this is in the range of 7–100 µeq g⁻¹. Thus, mobile-phase electrolyte concentration required for the separation will be very low and therefore mobile-phase background conductance will be very low. The second modification is to use a mobile-phase electrolyte that provides an eluent anion (for analyte anion separations) or cation (for analyte cation separations) with a high ion-exchange selectivity and an ionic equivalent conductance that differs significantly from the analyte ions. When these two adjustments in the methodology are made and a quality conductivity detector is used that has excellent conductivity offset capabilities and good temperature control, conductivity change due to the analyte gives a good S/N and therefore a favorable DL. Improvements in conductivity-detector electronic suppression of conductivity background and temperature control also contribute to the increased capabilities of nonsuppressed IC.

When the ion-exchange column exchange capacity and the mobile phase electrolyte and its concentration are optimized and a quality conductivity detector with good electronic offset, temperature control, and low internal cell volume is used, DLs by nonsuppressed IC often approach those obtained by suppressed IC. Since the exchange capacity is very low, care is needed to avoid column overload with the sample. A major advantage offered by nonsuppressed IC is that this approach is compatible with other types of detection in addition to conductivity. This broadens the scope of applications and sensitivity of nonsuppressed IC. Both direct and indirect absorption, fluorescence, and electrochemical detection methodologies can be used where applicable. In addition nonsuppressed IC is compatible with postcolumn reactions to convert the analytes into products that absorb, fluoresce, or are electrochemically active.

### 8 ELUENTS FOR NONSUPPRESSED ION CHROMATOGRAPHY

Table 4 lists several common electrolytes employed as mobile-phase electrolytes for the separation of anions. These represent a wide range of eluent strength but are not listed in order of eluent strength. Several have low limiting ionic equivalent conductances, particularly the salts of organic acids, and dilute solutions of these are compatible with conductivity detection. Others are more compatible with other detection strategies. Those that are multiprotic can be changed in eluent strength not only by concentration but also by pH which will determine the charge of the mobile-phase anion.

Borate salts and EDTA are mobile-phase electrolytes whose eluent strength can be varied over a wide range. Borate forms complexes with neutral and acidic polyhydroxy compounds such as sugars and tartaric or gluconic acid, respectively. The charge of the complex, which will determine the eluent strength, depends on the borate concentration, the polyhydroxy compound and its concentration, their ratio, and the pH. At a higher pH a mononegative 1:1 complex forms, which is a weak

| Table 4 Common eluent electrolytes for nonsuppressed ion chromatographic separation of anions |
|-----------------------------------|-----------------------------------|
| **Monoprotic acids** | **Multiprotic acids** |

| Alkane sulfonic acids | 1,3,5-Tricarboxybenzene |
| Mineral acids | EDTA |
| Sulfobenzoic acid | Sulfobenzoic acid |
| Sulfophthalic acid | |

eluent, low in conductivity, and therefore suitable for conductivity detection. EDTA is a tetraprotic acid and will be present in the mobile phase as a \(-1\) to \(-4\) anion depending on the pH. It is a strong eluent anion as a multivalent anion and is suitable for the elution of highly retained anions, such as polyphosphate analyte anions.

While a strong base, such as a NaOH or KOH mobile phase is easily used in anion exchanger separations by suppressed IC, these strong base mobile phases are not suitable for nonsuppressed IC with conductivity detection because the OH\(^-\) has such a high ionic equivalent conductance. A salt of a weak acid is a much better mobile-phase electrolyte. A mobile phase containing a strong base, however, is preferred when separating anions of low anion-exchange selectivity or anions derived from very weak acids, such as HCN or H\(_2\)BO\(_3\), because OH\(^-\) provides a mobile phase of low eluent strength. If a strong base is used, typically a detection method other than conductivity is used.

Electrolytes for the nonsuppressed IC separation of anion cations are fewer in number compared to nonsuppressed anion IC. A strong mineral acid mobile phase, such as HCl or HNO\(_3\), can be used but is incompatible with conductivity detection, if low DLs are required, because of high ionic equivalent conductance caused by H\(^+\). Buffered solutions of organic bases, such as benzylamine, pyridine, aniline, pyridinecarboxylic acid, and 1,2-ethanediol, are used to obtain the protonated base as the mobile phase electrolyte cation. Ethylenediamine with tartaric acid or \(\alpha\)-hydroxybutyric acid, oxalic acid/citric acid mixtures, and pyridine-2,6-dicarboxylic acid eluents are also used and provide both a strong eluent cation and complexing conditions. If multiprotic bases are used, such as ethylenediamine, phenylenediamine, DAP, or polyanion, than multivalent mobile-phase cations are obtained that are much higher in eluent strength depending on mobile-phase pH and pK\(_b\) values for the base. Quaternary ammonium (R\(_4\)N\(^+\)) salts, which can be strong mobile-phase cations depending on the structure of R, can be used but these also can undergo interaction with the cation exchanger matrix particularly if it is a PS-DVB polymeric-based cation exchanger. Mono and divalent inorganic cations provide a wide range of eluent strength. However, they are not usually employed with conductivity detection but are applicable to other detection modes. For example, Cu\(^{2+}\) or Ce\(^{3+}\) are both strong eluent cations (Ce\(^{3+}\) > Cu\(^{2+}\)) and are good mobile-phase electrolytes for the separation and resolution in the nonsuppressed separation of mono and divalent cations on a cation exchanger. Both Cu\(^{2+}\) and Ce\(^{3+}\) absorb, and thus, detection by indirect absorbance detection is possible. The Ce\(^{3+}\) also fluoresces and sensitivity is better with Ce\(^{3+}\), if an indirect fluorescence detection mode is employed.

9 DETECTION IN ION CHROMATOGRAPHY

Most detection strategies used in LC are applicable to IC separations. However, conductivity detection is the detection method of choice in virtually all suppressed IC separations since the suppression strategy overcomes the limiting effects of a mobile-phase conducting background (see Figure 5a and b). The conductance cell contains microelectrodes; consequently, cell volume is very small often corresponding to a few nanoliters and cell contribution to band broadening is small. Response is rapid, reproducible, sensitive (about \(5 \times 10^{-9}\) g mL\(^{-1}\)), and has a linear dynamic range of over three orders of magnitude provided the conductivity cell temperature is constant. While conductivity detection is also widely applied in nonsuppressed IC, other detection strategies are equally as important.

Spectroscopic detection methodology is second to conductivity detection in IC separations and is frequently used with nonsuppressed IC separations. Many inorganic and organic analyte ions absorb in the UV (ultraviolet) or visible region and a direct detection of absorbance change due to change in analyte ion concentration is straightforward. Fluorescence on the other hand is more selective since fewer analyte ions, particularly inorganic analyte ions, will fluoresce. DLs are specific to the analyte ion and will depend on its molar absorptivity for the former detection mode and the fluorescence yield in the latter.

Both absorption and fluorescence detection can be used in a direct or indirect mode. In the direct detection mode, absorbance or fluorescence of the analyte ion is determined in the presence of little or no absorbance or fluorescence in the background. As analyte ion concentration increases, its absorbance or fluorescence increases resulting in the analyte band appearing as a positive peak in the chromatogram. The peak height and peak area are proportional to analyte ion concentration and this correlation is the basis for calibration and subsequent determination of unknown samples of the same analyte ion. In the indirect detection mode the mobile-phase electrolyte absorbs or fluoresces and the analyte ion does not. Since the analyte ion competes with the electrolyte ion of the same charge for the ion-exchange site, a decrease in absorbance or fluorescence, which is due to this exchange competition, is observed on an absorbing or fluorescent background. Thus, negative detection peaks for the separated analyte ions are obtained in the chromatogram whose peak heights and
areas are proportional to each analyte ion concentration. If analyte anions are being separated, the mobile-phase electrolyte must provide an absorbing or fluorescing anion, while for cation separations the electrolyte cation must absorb or fluoresce. Indirect detection strategies are also feasible when using ion interaction reagents as illustrated later. The essential criteria that must be met for calibration, and the handling of the data in these direct and indirect detection strategies in quantitative determination applications is reviewed elsewhere.\(^1\)

Atomic spectroscopic detection strategies are useful in IC separations but limited to those kinds of analyte ions that can be atomized into the vapor state following the separation. Thus, both atomic emission and absorption methodologies are selective rather than universal detection strategies. These modes of detection have been shown to be both sensitive and reliable, where applicable, in IC separations. Of particular interest is detection by inductively coupled plasma mass spectrometry (ICPMS) since both qualitative identification and quantitative determination is possible with this detection system.

Another detection strategy that is vital in IC separations, particularly in the detection of inorganic ions, is a postcolumn reaction that produces a species that absorbs, fluoresces, or is photoluminescent. In this strategy the column effluent containing the separated analyte ions is combined with reagents postcolumn in a controlled way and the conditions are adjusted to produce the detector-active species. For inorganic analyte cations the reaction is often one that involves a formation of a detector-active complex. A successful postcolumn reaction must be reproducible and therefore careful control of the reaction conditions is vital. Typically, reaction time, temperature, pH, mixing rate, and reagent concentrations are parameters that must be optimized according to the chemical reaction and these details are discussed elsewhere.\(^{1–5}\)

Table 5 lists several postcolumn reagents that are routinely used for postcolumn detection in the IC separation of inorganic analyte anions and cations. Since detection is determined by the chemical reaction, selectivity can be incorporated into the detection step by using a reagent for the postcolumn reaction that is selective in its chemistry.

10 APPLICATIONS OF ION CHROMATOGRAPHY

IC is an indispensable analytical technique for the determination of common inorganic and organic analyte ions. As indicated in Figure 1 the method is rapid, reproducible, has excellent DLs and is applicable to trace quantities, can be insensitive to sample matrices, is applicable to complex mixtures, and is accurate and precise. For anion analysis IC is the method of choice for both simple and complex mixtures and has for the most part replaced chemical and other instrumental methods for anion analysis. For cation analysis IC is a companion method to emission and absorption spectroscopic methodologies, but IC does have the advantage of being more applicable to simultaneous multication analysis.

IC is vital to water analysis and frequently is the basis for officially approved methods. It is a routine method in studying drinkable water and rain water. Any industry, such as environmental, clinical, agricultural, pulp and paper, mining, chemical, pharmaceutical, power plant, electronic, and others, that depends on water quality will utilize IC in its analytical laboratories. Numerous examples are in the literature demonstrating the importance of IC in water quality studies. For example, Figure 9(a) and (b) illustrate anion analysis of drinking water and rain water, respectively, where the separation is complete in minutes, while Figure 9(c) shows the separation of the transition metals in an industrial wastewater sample. Suppressed conductivity is used in Figure 9(a) and (b). In Figure 9(c) the transition metals are detected via a postcolumn reaction. Following the separation on the cation exchanger the metal ions are...

(a) An aqueous 0.15 mM NaHCO₃, 2.0 mM Na₂CO₃ mobile phase at 2.0 mL min⁻¹ with 25 µL injection on a Fast-Sep anion-exchange column and suppressed conductivity detection. (b) An aqueous 2.8 mM NaHCO₃, 2.2 mM Na₂CO₃ mobile phase at 2.0 mL min⁻¹ with 50 µL injection on a IonPac AS4 anion-exchange column and suppressed conductivity detection. (c) An aqueous 50 mM H₂C₂O₄, 95 mM LiOH mobile phase at 1.0 mL min⁻¹ with 50 µL injection on a IonPac CS5 cation-exchange column with detection at 520 nm after a postcolumn reaction with PAR. (Reproduced by permission of Wiley-VCH from J. Weiss, *Ion Chromatography*, 349, 352, and 357.)

The excellent resolving power of IC is demonstrated in Figure 10 where 36 analyte anions are separated in about 30 min. Figure 10 also shows that IC is applicable: (1) to the separation of the more highly retained multivalent anions, (2) to organic anions such as the simple carboxylic acids which are important in the food and health sciences, and (3) that gradient elution is readily carried out with suppressed IC using conductivity detection. Although not discussed here gradient elution is also a viable elution strategy with nonsuppressed IC.²⁻⁵

IC is applicable to ultratrace analysis as shown in Figure 11(a) and (b). Often in these trace-analysis applications concentration of the analyte is required and the IC instrumentation is modified to include this operation. An example of IC trace analysis is illustrated in Figure 11(a), where the IC chromatogram for the determination of SO₄²⁻ in pure NaCl is shown. The Cl⁻ is removed by a precolumn and the SO₄²⁻ is detected after separation on an anion exchanger by suppressed conductivity. If required, Br⁻ and NO₃⁻ can also be determined but absorption detection would be more sensitive. Figure 11(b) illustrates the IC chromatogram for the determination of transition metals in 50% NaOH. The trace metals are concentrated on a precolumn, then separated by cation exchange, and subsequently detected postcolumn by absorption after reaction with PAR.

11 ION EXCLUSION CHROMATOGRAPHY

IEC is an ion-exchange method which allows the separation of ionic analytes from nonionic analytes and
is most often employed in the separation of mixtures of weak acids or bases. Ordinary high-capacity ion exchangers, usually the PSDVB type exchangers, are used. Weak acid analytes are separated on strong acid ion exchangers and weak bases are separated on strong base ion exchangers. Instrumentation for HPLC is used in IEC and detection is often by conductivity with or without suppression or by absorbance if the analytes are chromophoric.

While ion exchangers are used as the stationary phase in IEC, an exchange of ions is not responsible for the separation as the analytes travel through the column in the mobile phase. Consider the case where the weak acid acetic acid is the analyte, the mobile phase is an aqueous HCl solution, and the stationary phase is a PSDVB-SO$_3^-$H$^+$ cation exchanger. A simplified schematic illustrating what happens in the column is shown in Figure 12. The system is composed of three main components: one is the solid PSDVB polymeric network, the second is the stationary phase represented by the hydrated $-\text{SO}_3^-$H$^+$ sites, and the third is the mobile phase traveling around and between the exchanger particles. A Donnan-like membrane is established through which certain species only are able to penetrate. Neutral molecules penetrate and ions similar in charge to the co-ions (H$^+$ in Figure 12) pass into the exchanger resin phase, but ions of similar charge to the ionogenic group, for example C$_2$H$_3$O$_2^-$ in Figure 12, do not. The amount of ionized and neutral undissociated forms of the analyte will depend on the analyte's dissociation constant. Strong acid (and base) analytes, which are completely dissociated, are electrostatically repulsed and travel with a volume of mobile phase that corresponds to the column void volume. Partially dissociated analytes, such as acetic acid in Figure 12,
penetrate into the resin phase and are therefore retarded in their movement through the column. Elution of the partially dissociated analytes will often correspond to their ionization constants; that is the least dissociated travels the slowest through the column.

While dissociation is a key factor which influences analyte movement through the column in IEC, other factors are also significant depending on the analyte and the ion exchanger used for the IEC separation. Other principal contributing factors influencing analyte retention and elution order are interaction of the analyte with the exchanger matrix (adsorption), analyte size (size exclusion), and polar interactions between the analyte and the exchanger ionogenic group. Because of these interactions, which can be significant, certain neutral molecules can also be retained and resolved on ion exchangers.

IEC is widely used for the separation of weak organic acids. The role of the mobile phase is to dissolve the sample and act as a carrier of the analytes through the column. Often water is the mobile phase. Since dissociation is a key factor in IEC, ionization of weak acid analytes can be suppressed to enhance retention and resolution by including a mineral acid, for example HCl or H₂SO₄, in the mobile phase. Also, acetonitrile or alcohols are added to the mobile phase to increase analyte solubility, influence dissociation, and/or to alter weak acid analyte–exchanger matrix interactions.

IEC is widely used to separate complex mixtures of weak organic acids. In addition IEC is a good method for separating carbohydrates, aldehydes, ketones, and alcohols as neutral molecules. Because of these kinds of application IEC is invaluable as a separation method in the food/beverage industry and in the health sciences.

12 ION INTERACTION CHROMATOGRAPHY

Charge on an organic analyte sharply reduces its retention on a reversed stationary phase often leading to low retention and poor resolution on the reversed stationary phase. The scope of reversed-phase HPLC can be broadened when a lipophilic ion with a charge opposite to the analyte ion charge is included in the mobile phase. Increased retention, selectivity, resolution, and even an increased number of detection options are often realized. This separation strategy to enhance retention and resolution is particularly important in the application
of reversed stationary phases to the separation of mixtures of biological molecules containing acidic or basic groups.

These advantages are also realized when a lipophilic ion opposite in charge is added to the mobile phase to increase retention and resolution in the separation and determination of inorganic and simple organic anions and cations on a reversed stationary phase. This strategy, which is often called IIC or ion pair chromatography, is a useful alternative separation methodology to IEC. To separate analyte anions, a lipophilic cation, such as a tetraalkylammonium salt (for example, $R_4N^+$ Cl$^-$) is added to the mobile phase, while to separate analyte cations, a lipophilic anion, such as a long alkyl-chain sulfonic acid (for example $RSO_3^-$H$^+$), is added to the mobile phase. Several equilibrium steps contribute to the overall retention of the analyte ion, thus several column and mobile-phase parameters must be optimized and carefully controlled to obtain reproducible separation results. These include pH if analytes and the lipophilic ion are weak acids or bases, buffer components and concentration, ionic strength, selectivity of counterions, mobile-phase organic solvent/water ratio, type of organic solvent, hydrophobicity of the R group in the lipophilic ion, concentration of the lipophilic ion, and the type of reversed stationary phase used.$^{(23,24)}$

Either silica reversed stationary phases or PSDVB reversed-phase adsorbents are suitable stationary phases. The former offers the major advantages of better mass transfer, better column efficiency, and a better and reproducible stationary-phase surface. The latter offers pH stability throughout the pH range, often higher analyte retention, and larger analyte loading capacity.$^{(2,3,23,24)}$

Much research has gone into establishing a retention model that is consistent with the experimental results. For a mobile phase that is largely aqueous and buffered, a lipophilic salt that readily dissociates and is well below its critical micelle concentration and modest in ionic strength, analyte-ion retention on the reversed stationary phase can be described by the ion interaction model. When the mobile phase containing an appropriate concentration of the lipophilic ion, buffer, and ionic strength electrolyte in a mixed organic modifier/water solvent are passed through the reversed stationary phase column, an equilibrium amount of the lipophilic ion and its counterion are maintained on the reversed stationary-phase surface as a double layer. A schematic illustration of the key elements of this model for the case where $R_4N^+$Cl$^-$ is the mobile phase lipophilic ion that is continuously passed through the column is shown in Figure 14. When analyte anions represented by $X^-$ in Figure 14 enter the column they compete with $C^-$ in the diffuse secondary layer for the $R_4N^+$ sites. Differential migration of the different analyte anions occurs because of the preference the $R_4N^+$ shows for one analyte anion over another compared to $C^-$ just as if it were an anion-exchange selectivity. The similarity is such that the elution order for inorganic analyte anions follows the selectivity for strong base anion exchangers listed in Table 1.

Retention of analyte cations would be described by a similar model except that the lipophilic reagent would be anionic, for example $RSO_3^-$H$^+$. The primary layer on the reversed stationary phase is $RSO_3^-$ and the countercation in the secondary diffuse layer is $H^+$ or some other countercation provided by the mobile-phase buffer or ionic strength electrolyte. The analyte cations are therefore in competition with these cations in the diffuse layer.

Suppression methods can be used with analyte anion and cation separations by IIC to enhance conductivity detection. The MMS used when separating anions must contain an organic solvent-resistant membrane that is permeable to the lipophilic cation, for example $R_4N^+$, while the MMS for cation IIC separations must contain an organic solvent-resistant membrane permeable to the lipophilic anion, for example, $RSO_3^-$. Both are available commercially. Conductivity detection can be used with nonsuppressed IIC but DLs are usually not as good as those obtained by suppressed IIC. Figure 15 illustrates the chromatogram for the separation of inorganic anions on a $C_{18}$ reversed stationary phase with a quaternary ammonium salt as the mobile-phase lipophilic ion additive and nonsuppressed direct conductivity detection.

Direct absorbance or fluorescence detection is also a viable and widely used detection mode in nonsuppressed IIC when analytes absorb or fluoresce. Indirect absorption or fluorescence detection in IIC also provide good DLs when analyte ions do not absorb or fluoresce. In one approach the counterion, $C^-$ or $C^+$ (see Figure 14), to the lipophilic ion that is used for analyte anion or cation separations, respectively, absorbs or fluoresces.$^{(25)}$ As the analyte anion or cation band

---

**Figure 14** Schematic description of IIC. RSP, reversed stationary phase; $Q^+$, quaternary ammonium salt; $C^-$, counteranion; $X^-$, analyte anion.
moves down the column an equivalent amount of C− or C+ in the band is displaced by the analyte ion causing the absorbance or fluorescence in the band to be less relative to the background absorbance or fluorescence. Thus, the analyte peaks appear as negative chromatographic peaks. In a second approach the lipophilic ion itself absorbs or fluoresces. Figure 16(a) and (b) show a separation of inorganic and organic anions, respectively, on a reversed stationary phase using the [Fe(II)−(1,10-phenanthroline)3]2+ complex as the mobile phase lipophilic ion. As the analyte anions travel through the column an ionic strength difference in the analyte band relative to the background causes the amount of the complex to be greater in the analyte band. Thus, the analyte peaks appear as positive chromatographic peaks in the chromatogram.

REFERENCES

Micellar electrokinetic chromatography (MEKC) is a highly efficient miniaturized separation technique that is performed with the same experimental set-up that is used with capillary electrophoresis (CE). While the separation principle of CE is based on differences in the electrophoretic mobility of the solutes to be separated (only charged species can be separated), in MEKC separation is also based on differences in the distribution constants between two phases migrating at different velocity due to electrokinetic effects. The second phase is introduced into the separation electrolyte by adding an ionic surfactant (anionic or cationic) at a concentration above the critical micelle concentration (CMC). Aggregates of surfactant monomers (micelles) are present in the separation electrolyte. These aggregates have an electrophoretic mobility and are able to incorporate solutes or interact strongly with species dissolved in the surrounding medium.

MEKC extends the applicability of CE to neutral solutes. In addition, MEKC has been proven to be superior to CE in the separation of very complex mixtures of solutes with similar electrophoretic mobility, because of the various factors that are available for the manipulation of separation selectivity. Currently, MEKC can be regarded as a separation technique with a similar scope to that of reversed-phase high-performance liquid chromatography (RP-HPLC), having advantages over the latter concerning the efficiency of the separation system, separation speed, cost and tolerance to matrix constituents, as in MEKC no stationary phase is present that can be fouled by irreversible sorption of matrix constituents of the sample. Owing to the small injection volume (a few nanoliters) and small detection volume that is necessary to avoid intolerable instrumental band broadening, current MEKC instrumentation restricts the applicability of MEKC to the determination of those compounds in complex mixtures that are present in concentrations sufficiently high with respect to the limits of detection that can be obtained with such instrumentation.

1 INTRODUCTION

MEKC as a miniaturized separation technique for both charged and noncharged species was initially developed by Terabe et al.\(^1\),\(^2\) A theory of the separation principles involved is based mostly on investigations employing the anionic surfactant sodium dodecyl sulfate (SDS) as the micelle-forming agent in the separation electrolyte.\(^1\)–\(^5\) Otsuka et al.\(^4\) have shown that in place of SDS cationic surfactants [here dodecyltrimethylammonium bromide (DTAB)] can also be successfully employed in MEKC. Their results showed that the separation selectivity in MEKC can be altered easily by variation of the structure of the added micelle-forming agent.

Since these pioneering studies, MEKC has matured into a separation technique that can be employed for the quantitation of noncharged solutes in complex matrices or for the improvement of the separation selectivity in CE. Comprehensive introductions to MEKC are those by Vindevogel and Sandra\(^6\) and Terabe.\(^7\) More recent reviews on current state-of-the-art in MEKC are those by Khaledi\(^8\) and Muijselaar et al.\(^9\)

The instrumentation used in MEKC is identical to that employed in CE (see Capillary Electrophoresis). Separation takes place in a fused-silica capillary with an inner diameter < 100 µm and a length mostly varying between 20 and 100 cm. The capillary is filled with the separation electrolyte and is immersed at both
ends in vessels filled with the same electrolyte. A high voltage (up to 35 kV) is applied between two electrodes immersed in the same vessels. The sample is injected directly into the first segment of the capillary. In order to avoid instrumental band broadening, detection is effected in a short segment of the capillary, mostly using photometric or fluorimetric detection. The migration of analyte zones is caused exclusively by electrokinetic effects. Hydrostatic liquid flow in the capillary must be avoided. The temperature of the capillary must be controlled, and this can be done either with a thermostated liquid flowing in a jacket around the separation capillary or by placing the capillary in a thermostated chamber.

2 THEORY OF SEPARATION

2.1 Separation Principles

In MEKC, the separation electrolyte contains the background electrolyte (mostly two inorganic salts forming a buffer system) and an ionic surfactant (anionic or cationic) at a concentration above the CMC dissolved in water or a water–organic solvent mixture. According to the theory of zone electrophoresis, during separation the field strength inside the capillary remains constant along the capillary, assuming that the dissolved analytes do not contribute significantly to the charge transport inside the capillary. Thus the field strength can be calculated from the ratio of the voltage (ca. 10–35 kV) to the total length of the capillary (ca. 20–100 cm).

A fraction of the surfactant monomers (depending on the total surfactant concentration and the CMC) dissolved in the separation electrolyte forms aggregates (micelles), which are charged in the case of ionic surfactants. In the case of the most popular surfactant in MEKC, SDS, the mean aggregation number in pure water at room temperature is 64. There is a distribution of the aggregation number and this distribution is dependent on the temperature and on the composition of the surrounding medium.

As a result of electro-osmosis in bare fused-silica capillaries, the liquid in the capillary migrates with constant velocity towards the cathode. The direction of the electro-osmotic flow (EOF) is reversed in the case of a cationic surfactant in the separation electrolyte, because of the formation of hemimicelles at the capillary surface. The micelles are charged, thus have an electrophoretic mobility and migrate in the opposite direction to the EOF. Whether they are finally transported in the same direction as the EOF (but with lower velocity) or show an apparent velocity (apparent velocity of the micelles \( v_{MC} = \) electrophoretic velocity \( v_{ep} + \) electro-osmotic velocity \( v_{eo} \)), addition of vectors) in the opposite direction depends on the relation of the absolute electrophoretic velocity \( v_{ep} \) of the micelles to the absolute velocity \( v_{eo} \) of the EOF. In all instances, \( v_{eo} \) and \( v_{ep} \) of the micelles have opposite directions provided that neither \( v_{eo} \) nor \( v_{ep} \) equals zero.

Dissolved compounds can be present either in the micellar phase or in the surrounding phase. Hence they are distributed between two phases migrating at different velocities (see Figure 1). In the theory of MEKC it is assumed that the velocity of the micelles is not altered by the incorporation of a solute. Consequently, a neutral solute will migrate with an apparent velocity identical with \( v_{eo} \) as long as it is dissolved in the surrounding phase and will migrate with \( v_{MC} \) as long as it is incorporated into a micelle. Its apparent migration velocity \( v_{mig} \) is between \( v_{eo} \) and \( v_{MC} \) depending on the distribution constant \( K_{MS} \) between these two phases (see Figure 2). \( K_{MS} \) here is defined as the concentration of solute in the micellar medium divided by the concentration of this solute in the surrounding medium with regard to a section of the capillary. A solute with \( K_{MS} = 0 \) (i.e. a very polar

---

**Figure 1** Scheme illustrating separation mechanism in MEKC (anionic surfactant, normal elution mode).

**Figure 2** Development of solute zones in a separation capillary, normal elution mode, neutral solutes, \( K_{MS}(\text{solute 1}) > K_{MS}(\text{solute 2}) > K_{MS}(\text{solute 3}) \).
compound) can therefore be used to trace \( v_{eo} \), and a solute with \( K_{MS} \to \infty \) (i.e. a very nonpolar compound) can be employed to trace \( v_{MC} \).

In the case of solutes with an effective electrophoretic mobility different from zero (ions or solutes that are in a dissociation equilibrium with a charged species, i.e. acids or bases), separation is based not only on differences in \( K_{MS} \) but also on differences in the effective electrophoretic mobilities \( \mu_{ep} \) of the solutes. In this case, separation can be regarded as electrophoresis modified by the presence of micelles.

### 2.2 Separation by Distribution

In MEKC it is possible to separate neutral solutes that differ only in \( K_{MS} \). Figure 3 shows the separation of a mixture of 24 explosives (mostly nitrotoluenes) within 11 min. Separation by distribution between phases of different velocity is analogous to the separation process in chromatography. In analogy with chromatography, the phase surrounding the micellar phase is termed the mobile phase and the micellar phase is termed the pseudostationary phase, taking into consideration that the solute is transported not only by the mobile phase but also by the pseudostationary phase.

The retention factor \( k \) for a neutral solute is defined according to Equation (1):

\[
    k = \frac{t_{stat}}{t_{mob}} = \frac{t_R - t_{mob}}{t_{mob}}
\]

where \( t_{stat} \) = fraction of time present in the stationary phase, \( t_{mob} \) = fraction of time present in the mobile phase and \( t_R \) = retention time. It is important to note that \( t_{mob} \) does not equal the elution time of a nonretarded marker and it has to be calculated from Equation (2):

\[
    v_{mig} = \frac{t_{mob}}{t_R} v_{eo} + \frac{t_R - t_{mob}}{t_R} v_{MC}
\]

Taking into consideration that \( v_{mig} \), \( v_{eo} \) and \( v_{MC} \) can be replaced by \( t_R/L, t_0/L \) and \( t_{MC}/L \), respectively \( [t_0 = \text{elution time of a nonretarded marker (} K_{MS} \to \infty) \), \( t_{MC} = \text{elution time of a marker of the velocity of the micelles (} K_{MS} \to \infty) \) and \( L = \text{length of the capillary to the detector} \), Equations (1) and (2) can be transformed by rearrangement into Equation (3):

\[
    k = \frac{t_R - t_0}{t_0(1 - t_R/t_{MC})}
\]

In order to obtain \( k \), markers must be available that make it possible to determine \( t_0 \) and \( t_{MC} \). These markers are often thiourea or methanol for the measurement of \( t_0 \) and timepidium bromide or quinine hydrochloride (for anionic micelles) or Sudan III for the measurement of \( t_{MC} \).

Chen et al.\textsuperscript{(11)} have pointed out that in the presence of organic modifiers in the separation electrolyte, the determination of $t_{MC}$ with a single hydrophobic compound as marker is unreliable. Therefore, the determination of $t_{MC}$ based upon a homologous series has been proposed.\textsuperscript{(12)} Kuzdzal et al.\textsuperscript{(13)} proposed a procedure that can simultaneously determine $t_0$ and $t_{MC}$ based on the retention times of several molecules in a homologous series. They employed the homologous series of methyl to $n$-pentyl $p$-hydroxybenzoates. In their approach, errors associated with the selection of appropriate markers can be avoided.

In the normal elution mode, $t_0$ for a neutral solute can only have values between $t_0(k = 0)$ and $t_{MC}(k \to \infty)$; the time span between $t_0$ and $t_{MC}$ is also called the migration or elution window. This elution window limits seriously the peak capacity obtainable in MEKC. Often the ratio $t_0/t_{MC}$ is used as a descriptor of the elution window, as it reflects the velocity ratio of the two phases. As $t_0/t_{MC}$ decreases, the elution window increases.

If $v_{co} = 0$, then the analytes have to be transported by the micelles to the detector. Hence the EOF is not a prerequisite for MEKC. If $|v_{ep}|$ of the micelles $> |v_{co}|$, then those solutes with $k > -t_{MC}/t_0$ have to be transported by the micelles to the detector.\textsuperscript{(16)} For these solutes, the elution order is reversed with respect to the elution order obtained in the normal elution mode (the solute with the highest $K_{MS}$ elutes first). The elution mode in which the solutes are transported with the micelles to the detector has therefore been termed reversed-migration micellar electrokinetic chromatography (RMMEKC). In contrast to the normal elution mode, in RMMEKC the elution window is not limited.

All the above conclusions are valid only in the case of neutral, noncharged solutes with an effective electrophoretic mobility $\mu_{ep} = 0$. If $\mu_{ep}$ is not negligible, then the apparent velocity of this solute in the mobile phase will be different from $v_{co}$. Hence Equation (2) has to be replaced by Equation (4):

$$v_{mig} = \frac{t_{mob}}{t_{R}} (v_{co} + \mu_{ep}E) + \frac{t_{R} - t_{mob}}{t_{R}} v_{MC}$$

(4)

where $E$ = electric field strength.

The electrophoretic mobility has to be determined in a separate experiment with a separation electrolyte similar to that employed in MEKC without the presence of micelles. If $\mu_{ep}$ is known, it is possible to determine the true retention factor from the data already discussed for neutral solutes, replacing Equation (3) by Equation (5):

$$k = \frac{t_{R} - t_{OM}}{t_{OM}(1 - t_0/t_{MC})}$$

(5)

where $t_{OM}$ = migration time of a solute in the absence of micelles.

It is important to note that $t_{OM}$ is different from $t_0$. The magnitude $t_{OM}$ has to be calculated from $\mu_{ep}$ of the solute, the field strength $E$, the electro-osmotic velocity $v_{co}$ obtained with the micellar phase and the length $L$ to the detector, according to Equation (6):

$$t_{OM} = \frac{L}{\mu_{ep}E + v_{co}}$$

(6)

It should be noted, however, that, in MEKC, mobility data obtained with CE experiments have to be used with caution for calculating retention factors of charged solutes. Differences between true and calculated retention factors can arise from neglecting a fundamental difference between the composition of the mobile phase in MEKC and the electrolyte in CE, namely the presence of the surfactant monomer in the mobile phase at a concentration equal to the CMC in the case of MEKC.\textsuperscript{(15)}

### 2.3 Separation by Electrophoresis

In the case of solutes with non-negligible $\mu_{ep}$, the separation of two solutes is possible either if these solutes differ in the distribution constant $K_{MS}$ or in $\mu_{ep}$. Hence the addition of a surfactant to the separation electrolyte can be a valuable tool to effect the separation of charged solutes, if the selectivity obtained by electrophoresis is not sufficient, and also when electrophoresis remains the dominating effect.

From the viewpoint of electrophoresis, MEKC can be regarded as electrophoresis, with the micellar phase as an "interaction agent" influencing the effective mobility of the solutes.

For qualitative analysis (peak assignment), it can be useful to employ the pseudoeffective mobility $\bar{\mu}_{ep}$\textsuperscript{(16)} as a descriptor of a solute. This magnitude can be calculated from the elution time $t_R$ of the solute and the elution time $t_0$ of a non-retained marker (Equation 7):

$$v_{mig} = \frac{L}{t_{R}} = v_{co} + (\bar{\mu}_{ep}E) = \frac{L}{t_{0}} + (\bar{\mu}_{ep}E)$$

(7)

The advantage of $\bar{\mu}_{ep}$ calculated according to Equation (7) over $k$ calculated according to Equation (5) is that neither $t_{MC}$ nor the true effective mobility $\mu_{ep}$ have to be determined.

Ghowsi et al.\textsuperscript{(17)} termed $\bar{\mu}_{ep}$ the effective electrophoretic mobility of the solute. They defined the effective migration mobility of the solute $\bar{\mu}$, as the summation of the effective electrophoretic mobility of the solute $\bar{\mu}_{ep}$ and the electro-osmotic mobility $\mu_{co}$ (Equation 8):

$$\bar{\mu} = \bar{\mu}_{ep} + \mu_{co}$$

(8)

It is important to note that also a neutral compound has a pseudoeffective mobility if $k$ is different.
from zero. For a neutral solute the effective electrophoretic mobility as defined in Equation (7) can therefore be described in terms of the retention factor \( k \) and the electrophoretic mobility of the micelle \( \mu_{ep,MC}^{(17)} \) (Equation 9):

\[
\bar{\mu}_{ep} = \left( \frac{k}{1+k} \right) \mu_{ep,MC}
\]  

(9)

For charged and non-charged solutes, \( \bar{\mu}_{ep} \) can be related to the retention time \( t_R \) via Equation (10):

\[
t_R = \frac{L L_{tot}}{\left( \bar{\mu}_{ep} + \mu_{eo} \right) V}
\]  

(10)

where \( L \) = length to the detector, \( L_{tot} \) = total length and \( V \) = voltage. This equation is identical with that usually employed in CE and illustrates the impact of \( \mu_{eo} \) and other physical parameters on the migration time of a solute.

### 3 RESOLUTION OPTIMIZATION

#### 3.1 Resolution of a Peak Pair

For deriving the resolution equation for a pair of neutral solutes in the normal elution mode, Equation (3) has to be used instead of the term \( k = (t_R - t_0)/t_0 \) used in conventional chromatography. The resulting equation was derived by Terabe et al.\(^{(2)}\) [Equation 11]:

\[
R = \frac{\sqrt{N}}{4} \times \frac{\alpha - 1}{\alpha} \times \frac{k_2}{1 + k_2} \times \frac{1 - t_0/t_{MC}}{1 + (t_0/t_{MC})k_1}
\]  

(11)

where \( N \) = number of theoretical plates, \( \alpha \) = selectivity factor and \( k_1 \) and \( k_2 \) = retention factors of the first and second solute (according to the elution order) \( (\alpha = k_2/k_1) \).

In contrast to conventional liquid chromatography (LC), the resolution is dependent not only on the chromatographic efficiency, the selectivity and the retention factor, but also on the ratio \( t_0/t_{MC} \), which in the normal elution mode is smaller than unity. Consequently, in MEKC in the normal elution mode at identical \( N, \alpha, k_1 \), and \( k_2 \), the resulting resolution is always smaller than that obtainable with an immobilized stationary phase. The impact of \( t_0/t_{MC} \) on the resolution in comparison with conventional chromatography \( (t_0/t_{MC} = 0) \) is illustrated in Figure 4, where \( f(k) \) is plotted against \( k \), approximating \( k_1 = k_2 = k \). The term \( f(k) \) corresponds to the last two terms of Equation (11). It is also called the retention term and consists of the two terms containing the retention factor (Equation 12):

\[
f(k) = \frac{k}{1+k} \times \frac{1 - t_0/t_{MC}}{1 + (t_0/t_{MC})k}
\]  

(12)

**Figure 4** Dependence of \( f(k) \) on the retention factor \( k \) for different values of \( t_0/t_{MC} \) (given on each curve). (Reprinted with permission from S. Terabe, K. Otsuka, T. Ando, *Anal. Chem.*, 57(4), 834–841 (1985), Copyright 1985 American Chemical Society.)

With Figure 4, Terabe et al.\(^{(2)}\) have also shown that the resolution does not increase steadily with increase in the mean retention factor for the solutes to be separated (provided that \( N, \alpha \) and \( t_0/t_{MC} \) are constant), but reaches a maximum. By differentiation of Equation (12) with respect to \( k \) and setting the resulting expression equal to zero, Foley\(^{(18)}\) calculated that maximum resolution is obtained for a mean retention factor \( k = \sqrt{t_{MC}/t_0} \).

In the case of charged solutes, the resolution is affected by both differences in the effective electrophoretic mobilities of the solutes and differences in the retention factor. A resolution equation applicable to charged solutes was derived by Cortjens et al.\(^{(19)}\) This equation relates the resolution for a peak pair (normal elution mode) to the capacity factors and the \( t_{M0} \) values (see Equations 5 and 6). It can be used to gain insight into the separation mechanisms involved.

Zhang et al.\(^{(20)}\) presented a classification scheme that is restricted to the separation of neutral solutes. They defined the phase velocity ratio \( P_t \) according to Equation (13):

\[
P_t = \frac{t_{MC}}{t_0}
\]  

(13)

With this introduced magnitude, Equation (3) can be rewritten as Equation (14):

\[
t_R = t_0(k + 1) \times \frac{P_t}{k + P_t}
\]  

(14)
It is important to note that Equation (14) is valid for any value of $P_r$, $P_t$ can be negative based on the definition that the velocity is positive when the migration is towards the negative electrode and negative when it is towards the positive electrode.\(^{(5)}\) Hence a negative $t_{MC}$ or $t_0$ indicates that the micellar phase or the surrounding medium migrates towards the positive electrode. The same holds true for the migration time $t_R$. The absolute value of $t_R$ indicates the elution time of a solute, if the voltage is suitable.

According to the value of $P$, MEKC has been classified by Zhang et al. into eight cases, that can be simplified to six cases: (1) $P = 0$, (2) $0 < P < 1$, (3) $P = 1$, (4) $1 < P < \infty$, (5) $P \to \infty$ or $-\infty$ and (6) $-\infty < P < 0$.

The last term of Equation (11) corresponds to the column availability $A_{co}$ introduced by Zhang et al.\(^{(20)}\) (Equation 15):

$$A_{co} = \frac{P_t - 1}{P_t + k_1}$$

The normal elution mode corresponds to case (4). In this case $0 < A_{co} < 1$ (see Figure 4). Case (2) would represent the inverted normal elution mode, if a physical realization were possible. Both phases migrate in the same direction, but the micelles migrate faster than the EOF.

Case (5) corresponds to conventional chromatography with a mobile and a stationary phase. In this case $A_{co} = 1$. Case (1) corresponds to conventional chromatography if the micellar phase is regarded as the mobile phase and the surrounding phase as the stationary phase. As the micelles are in this case the nonpolar phase, this would correspond to normal-phase LC. In case (3), no separation is obtained, as both phases migrate with the same velocity, $A_{co} = 0$. In case (6), the column availability can be larger than unity. However, in case (6) the migration direction of a solute (towards the cathodic or the anodic end) depends on the retention factor. Case (6) has therefore also been termed the restricted elution mode for $k < -t_{MC}/t_0$.\(^{(6)}\) For $k > -t_{MC}/t_0$ it is identical with RMMEKC defined in section 2.2.

### 3.2 Adjustment of Retention Factors

As depicted in Figure 4, one optimization strategy for the separation of non-charged solutes with MEKC in the normal elution mode is to bring the retention factors of the solutes to be separated into the optimum range. This can be done by:

- variation of the pseudostationary phase/mobile phase phase ratio;
- employing a different surfactant;
- adding a modifier to the separation electrolyte that influences the distribution constant $K_{MS}$.

The retention factor $k$ is related to the pseudostationary phase/mobile phase phase ratio by Equation (16):

$$k = K_{MS} \frac{V_{mic}}{V_{sur}}$$

where $V_{mic}$ = volume of micellar phase and $V_{sur}$ = volume of surrounding medium. $V_{mic}$ can be determined from the total concentration of surfactant $c_{tot}$ minus the concentration of surfactant present as monomers (this corresponds to the CMC) and the molar volume $V_{sur}$ of surfactant present in the micellar phase\(^{(2)}\) (Equation 17):

$$\frac{V_{mic}}{V_{sur}} = \frac{\hat{V}_{surf}(c_{tot} - CMC)}{1 - \hat{V}_{surf}(c_{tot} - CMC)}$$

If $c_{tot} - CMC$ is small, $1 - \hat{V}_{surf}(c_{tot} - CMC)$ can be approximated by unity. Hence there is a linear relationship between the total surfactant concentration and the retention factor\(^{(2)}\) (Equation 18):

$$k = K_{MS}\hat{V}_{surf}(c_{tot} - CMC)$$

![Figure 5](image) Retention factor $k$ for $p$-nitrotoluene as a function of the concentration of the surfactant SDS in the separation electrolyte. $c$(Urea) = (○) 0; (△) 1; (●) 2; (□) 3; (▲) 4 mmol L$^{-1}$. Background electrolyte: 30 mmol L$^{-1}$ disodium tetraborate.
MICELLAR ELECTROKINETIC CHROMATOGRAPHY

considerably above the CMC. A too low volume of micellar phase might cause band broadening due to overload of the pseudostationary phase. The upper concentration limit is given by the solubility of the surfactant in the surrounding phase (precipitation of surfactant must be avoided) and by limitations concerning the electric current tolerated by the experimental set-up. The addition of anionic surfactant to the separation electrolyte increases considerably its specific electric conductivity. Consequently, instrumental parameters such as the inner diameter of the capillary, total length of capillary and efficiency of the thermostating system can have an impact on the upper concentration limit.

In the case of non-polar analytes it might be impossible to bring the retention factors of the solutes to be separated into the optimum range only by varying the total surfactant concentration. In these cases it is possible to use a modifier, mostly an organic solvent or urea or urea and an organic modifier simultaneously. The modifier reduces the distribution constant $K_{MS}$. In Figure 5, the slope of the regression line decreases with increasing content of urea in the separation electrolyte. As the $x$-axis intercept corresponds to the CMC and there is virtually no dependence of the CMC on the modifier concentration, assumptions are corroborated that in the case of urea as modifier there is only a small impact of the urea concentration on the CMC of SDS. Only a few data are available on the impact of the modifier on the CMC or on the micelle structure (i.e. mean aggregation number, distribution of aggregation number, shape). There is an indication that the addition of urea and of acetonitrile (below a critical concentration) does not alter the CMC of SDS, largely in electrolytes that are usually employed in MEKC. Consequently, it can be assumed in those cases that the phase ratio can be approximated to be constant independent of the modifier content.

The large impact of organic modifiers on the retention factors is illustrated in Figure 6(a) and (b), comparing the MEKC separation of dansylated aliphatic amines effected with a separation buffer containing no organic modifier and effected under identical experimental conditions with a separation buffer containing a volume concentration of acetonitrile of 15% (v/v) and a concentration of urea of 4.1 mol L$^{-1}$. The concentration of the surfactant SDS was kept constant at 20 mmol L$^{-1}$. The retention factor of dansylated 1-aminohexane can be reduced (at a constant surfactant concentration) from 185 obtained under the conditions of Figure 6(a) to 1.26 with a separation buffer containing a concentration of acetonitrile of 15% (v/v) and a concentration of urea of 5.0 mol L$^{-1}$.

The retention factors of solutes can also be drastically reduced by adding cyclodextrins to the separation electrolyte. Terabe et al. termed this variant of MEKC cyclodextrin-modified micellar electrokinetic chromatography (CDMEKC). With this method they were even able to separate chlorinated benzene congeners and other highly hydrophobic solutes.

A third possibility for varying the retention factor is the selection of the surfactant used. The micelles or multimers of bile salts (cholates and taurocholates) show a solubilizing power that is usually much smaller than that of SDS. They have therefore been employed for the separation of very nonpolar solutes. Their chiral properties have also been used for enantiomeric resolution.
3.3 Widening of the Migration Window

The considerations outlined in section 3.1 have shown the strong impact of the ratio \( \frac{t_{MC}}{t_0} \) (also termed the phase velocity ratio, \( P \)) on the column availability \( A_{\infty} \), and consequently the resolution obtainable [Equation 19]:

\[
R = \sqrt{\frac{N}{4}} \times \frac{\alpha - 1}{\alpha} \times \frac{k_2}{1 + k_2} A_{\infty}
\]  \hspace{1cm} (19)

Equation (19) corresponds to Equation (11).

In the normal elution mode for neutral solutes, \( t_0 \) is restricted to the migration or elution window with the limits \( t_0 \) and \( t_{MC} \). From Equation (11) and Figure 4 it can be deduced that in this mode the resolution will be improved if the ratio \( t_0/t_{MC} \) is lowered. The limited migration window limits also the peak capacity of the separation system (peak capacity = maximum number of substances that can be separated by a system). For rapid separations, however, a small resolution window [corresponding to a steep gradient in gradient elution high-performance liquid chromatography (HPLC)] can also have advantages.

An overview on parameters controlling the elution window in MEKC with an anionic surfactant (mostly SDS) as micelle-forming agent was given by Mujselaar et al.\(^{[29]}\) These parameters include buffer pH, ionic strength, capillary surface modifications, alkyl chain length of the surfactant, surfactant concentration and organic modifiers. Principally, two effects can be used to widen the migration window: (1) increase in the electrophoretic velocity of the micelles and (2) reduction of the electro-osmotic velocity. Although effect (1) has advantages over (2) as it widens the migration window without prolonging the hold-up time of the system, thus increasing the analysis time only slightly, there are difficulties in its physical realization. Hence effect (2) is mostly employed for improving the migration window.

It should be noted, however, that by addition of urea to a separation electrolyte containing SDS it is possible to widen the migration window significantly, while \( t_0 \) is only marginally increased.\(^{[23,24]}\) Other organic modifiers (e.g. methanol and acetonitrile) also widen the migration window.\(^{[29,30]}\) These modifiers, however, also have a large impact on the retention factors of the solutes. They are, therefore, predominantly used for adjusting retention factors.

When a separation electrolyte is used that contains an anionic surfactant as micelle-forming agent, the electrokinetic potential and consequently the electro-osmotic velocity is not influenced by the formation of hemimicelles on the negatively charged fused-silica surface. In this case the electro-osmotic mobility is largely dependent on the pH, whereas the electrophoretic mobility of the micelles can be expected to be virtually independent of the pH.\(^{[29]}\) Thus in MEKC with an anionic surfactant the pH is a very powerful tool for regulating \( t_{MC}/t_0 \) at the expense of increasing the hold-up time. Otsuka and Terabe\(^{[31]}\) have shown that with SDS as micelle-forming agent the direction of the apparent velocity of the micelles is changed at pH 5.0. Whereas at high pH the absolute electrophoretic mobility \( |\mu_{ep}| \) of the micelles is smaller than the absolute electro-osmotic mobility \( |\mu_{eo}| \) corresponding to the normal elution mode, at low pH \( |\mu_{ep}| \) is larger than \( |\mu_{eo}| \) corresponding to the restricted elution mode or reversed elution mode.\(^{[31,32]}\)

Janini et al.\(^{[33]}\) have shown that coating of the inner surface of the fused-silica capillary with a linear polyacrylamide can be used to reduce drastically the electro-osmotic mobility. In this case the reversed elution mode can also be obtained at higher pH.

When a cationic surfactant is used as micelle-forming agent in MEKC, \( \mu_{eo} \) is reversed by the hemimicelles that are formed by the surfactant monomers on the fused-silica surface. Hemimicelles are aggregates of surfactant monomers that are adsorbed on the solid at the solid–liquid interface.\(^{[34]}\)

Currently, cationic surfactants are rarely employed in MEKC separations, partly because in the normal elution mode the migration window is generally much smaller when using an alkyltrimethylammonium bromide as cationic surfactant than the migration window that can be obtained with SDS as the micelle-forming agent.\(^{[4]}\) Cationic surfactants, however, have a complementary selectivity to other anionic surfactants.\(^{[35,36]}\) Moreover, there is indication that cationic surfactants can have advantages over anionic surfactants concerning repeatability in routine analysis.\(^{[37]}\) However, means of improving the migration window in MEKC with cationic surfactants have scarcely been investigated so far.

The pH dependence in the presence of a cationic surfactant differs strongly from that observed with an anionic surfactant. Crosby and ElRassi\(^{[38]}\) determined the dependence of \( \mu_{eo} \) on pH with a separation electrolyte containing hexadecyltrimethylammonium bromide (CTAB). Under the conditions of their measurements, the width of the migration window remained virtually unchanged as the pH was varied between 4.5 and 9.0.

In order to widen the migration window, additives (e.g. inorganic salts with divalent metal cations) to the separation electrolyte can be used that are selectively adsorbed on the fused-silica surface, competing with the surfactant monomers for positions in the electric double layer.\(^{[39,40]}\) The result is a reduction in the electro-osmotic mobility \( \mu_{eo} \). If \( \mu_{eo} \) is decreased while the electrophoretic mobility \( \mu_{ep} \) of the micelles is maintained, the result will be an improvement in the migration window. In Figure 7(a)
3.4 Selectivity

A major advantage of MEKC is its flexibility. The composition of the separation electrolyte and, in particular, the pseudostationary phase can easily be changed by rinsing the capillary. Hence MEKC is more flexible than a chromatographic technique with an immobilized stationary phase. The composition of the mobile phase and the composition of the pseudostationary phase can easily be adapted to the respective separation problem.

In MEKC, the selectivity for separations of neutral solutes is mainly dependent on the surfactant system used. Various types of surfactants have been used in MEKC over the past 10 years: charged surfactants (anionic or cationic), non-ionic and zwitterionic surfactants (see Table 1). In order to separate noncharged solutes, charged surfactants must be used. Surfactants with a zero net charge can be used along with an ionic surfactant as selectivity modifier forming mixed micelles with the charged moieties. Nonionic and zwitterionic surfactants can also be used alone to modify the selectivity for the separation of charged solutes.

\(^c\) Data from Crosby.\(^{38}\)
\(^e\) Data from Khaledi.\(^{8}\)

SC, sodium cholate; Brij\(^{\circ}\) 35, polyoxyethylene(23)dodecyl ether.
The fundamental importance of selectivity for resolution is represented by the presence of the selectivity factor \( \alpha \) in Equation (11). For neutral solutes the choice of surfactant is the most important consideration in optimizing selectivity. Poole and Poole\(^{43}\) have shown that the experimental parameters surfactant concentration, buffer concentration, buffer pH, temperature and choice of buffer have little influence on the selectivity (for neutral solutes and SC as surfactant). There is some alteration in the selectivity with organic modifiers in the separation electrolyte. However, the choice of organic solvent (5%, v/v) as modifier (methanol, acetonitrile, tetrahydrofuran, propan-2-ol) seems to be virtually without influence on the selectivity.

For rapid method development in MEKC, it is therefore highly desirable to have a set of surfactants with complementary selectivity. The following constraints have to be respected: (1) their Krafft points must be lower than ambient temperature; (2) their CMC in the separation electrolyte (different from that in pure water) should not exceed 20–30 mmol L\(^{-1}\); (3) their solubility in aqueous buffers at ambient temperature must be sufficient. These constraints can mostly be fulfilled by only one member of a homologous series with varying alkyl chain length (see Table 1).

Yang and Khaledi\(^{42}\) and Yang et al.\(^{43}\) employed linear solvation energy relationships (Kamlet–Taft solvatochromic model) in order to make an attempt to classify surfactants according to the type of solute–surfactant interaction. They concluded that hydrogen-bonding interactions play a major role in providing different chemical selectivity among the five surfactant systems that they investigated.

Poole and Poole\(^{41}\) employed the solvation parameter model, that is in use in areas of retention modeling in chromatography, in order to characterize the surfactant selectivity in MEKC. In this model the solvation process is described in terms of fundamental intermolecular interactions with solute or solvent properties determined from equilibrium processes. Employing data obtained by applying this model, they suggested a working list for surfactants for selectivity optimization in MEKC: SDS, SC, lithium perfluoro-octanesulfonate, N-dodecanoyl-N-methyltaurine and TTAB.\(^{44}\)

Muijselaar et al.\(^{45}\) introduced the retention index concept for application in MEKC. They defined the retention index \( I \) of a solute according to Equation (20):

\[
I = 100z + 100 \frac{\log \left( \frac{t_s - t_0}{\Delta t_c - t_s} \right)}{\log \left( \frac{t_{s+1} - t_0}{\Delta t_c - t_{s+1}} \right)}
\]

(20)

where \( z \) = number of carbon atoms in a member of a homologous series eluted before the solute, \( t_s \) = elution time of a solute, \( t_0 \) = hold-up time, \( t_{MC} \) = migration time of the micelles, \( t_s \) = elution time of a neighboring member of a homologous series (eluted before the solute) and \( t_{s+1} \) = elution time of a neighboring member of a homologous series (eluted after the solute). The retention index defined according to Equation (20) is not dependent on the phase ratio, i.e. it is independent of the surfactant concentration. Alkylbenzenes and alkyl aryl ketones can be used as retention index standards in MEKC. The retention index is useful as a parameter for peak identification.

In analogy with the Rohrschneider–McReynolds scale in gas chromatography (GC), the retention index can be also employed for the characterization of pseudostationary phases.\(^{46}\)

Fine tuning of the selectivity can be performed by employing mixed micelles. To this end, Little and Foley\(^{47}\) employed a mixed micellar system consisting of SDS and Brij\(^{40} \) 35. The variation of selectivity with composition for a mixed-micellar buffer has been studied by employing the solvation parameter model.\(^{48}\) The change in selectivity associated with the addition of Brij\(^{40} \) 35 to separation electrolytes containing SDS has been reported by Rasmussen et al.\(^{49}\) The main disadvantage of this approach is an unfavorable narrowing of the migration window in the normal elution mode caused by the integration of the nonionic surfactant into the anionic micelles, thus reducing the electrophoretic mobility of the micelles. As can be seen from Equation (11), this effect (increase in \( t_0/t_{MC} \)) can counteract the resolution improvement through increase in \( \alpha \).

A general overview on techniques that can be employed to manipulate the selectivity in MEKC was given by Terabe.\(^{50}\) These techniques comprise the choice of the surfactant and the use of mixed micelles, but also additives such as ion-pair reagents, urea, organic solvents and metal ions. For ionizable solutes a strong impact on selectivity is given by the pH of the separation electrolyte. An extensive investigation on the migration behavior of acidic solutes has been presented by Khaledi et al.\(^{51}\) Their phenomenological approach assumes that the parameters, retention factor and electrophoretic mobility, of an acidic solute are the weighted average of the parameter of the solute in the dissociated and the undissociated forms. By variation of the pH, the dissociation equilibrium is influenced, and thus also the effective retention factor and the effective electrophoretic mobility. Khaledi et al. developed equations describing the relationships between the two migration parameters – retention factor and mobility – on the two experimental parameters: pH and surfactant concentration. The same approach can be employed for an understanding of the dependence of the migration behavior of basic solutes on pH.\(^{52}\)

If basic solutes are separated in MEKC with an anionic surfactant or acidic solutes are separated in MEKC with a
cations is about 200 000–300 000.

radial temperature gradient effects and electrophoretic sorption–desorption kinetics, intermicelle mass transfer, ascribed to five mechanisms: longitudinal diffusion, radial temperature gradient effects and electrophoretic

For the separation of acidic solutes (partly or fully dissociated) or basic solutes (partly or fully protonated), the selectivity can be completely altered (at constant pH) if a cationic surfactant is used instead of an anionic surfactant.\(^4\) Nishi et al.\(^5\) have demonstrated that the selectivity can also be effectively manipulated in MEKC with an anionic surfactant (separation of carboxylic acids and cationic and zwitterionic substances) by addition of an ion-pair reagent (tetraalkylammonium bromide). By addition of the ion-pair reagent to the separation electrolyte containing SDS as micelle-forming agent, the migration time of cationic solutes is decreased and the migration time of anionic solutes, in contrast, is increased at about constant electro-osmotic velocity.

3.5 Efficiency

The efficiency of a chromatographic system is quantified by the number of theoretical plates per column, \(N\). A high efficiency is important for the resolution of closely related compounds [see Equation 11], for rapid separations and for obtaining a sufficiently high peak capacity. MEKC can be characterized as a separation method with inherently high efficiency – one of its main advantages over conventional chromatographic techniques. The number of theoretical plates per capillary (length to the detector 50–70 cm) obtained in MEKC for retarded \((k = 1–5)\) neutral solutes under routine conditions is about 200000–300000.\(^54,55\)

Terabe et al.\(^54\) have studied in detail for MEKC the band-broadening phenomena that occur in the separation capillary during a run. These phenomena have to be divided into two groups: the extra-column and the in-column effects. Extra-column effects comprise the injection volume, the cell volume of the detection part of the capillary, the time constant of the detector and the sampling rate of the data system or the response of the recorder pen. With suitable injected plug length and adequate in-column detection, extra-column effects can be kept low.

The causes of in-column band broadening can be ascribed to five mechanisms: longitudinal diffusion, sorption–desorption kinetics, intermicelle mass transfer, radial temperature gradient effects and electrophoretic dispersion of the micelles (heterogeneity in micelle mobilities). At slow velocity of the solute zones, longitudinal diffusion is the dominant factor, whereas at higher velocities sorption–desorption kinetics and heterogeneity in micelle mobilities become significant factors. For separations in the normal elution mode, Terabe et al.\(^54\) recommend working with an electro-osmotic velocity >1 mm s\(^{-1}\) and keeping the retention factors to <5.

The influence of the surfactant concentration on efficiency is controversially discussed in the literature.\(^54,55,57\) Yu et al.\(^57\) did not obtain a significant dependence of \(N\) on the SDS concentration of the separation electrolyte for moderately retarded solutes in the concentration range 15–100 mmol L\(^{-1}\). They showed that it is possible in MEKC to obtain an efficiency that is limited only by the injected sample plug length and longitudinal diffusion. At very high electro-osmotic velocity, factors corresponding to the resistance in mass transfer known for conventional chromatography are dominant, thus resulting in a drastic decrease in \(N\) with increasing electro-osmotic velocity.\(^55,57,58\)

In order to use the high efficiency obtainable in MEKC, band broadening due to inadequate buffer leveling has to be avoided. If the buffer levels in the inlet and the outlet vessel are not identical, a laminar flow in the capillary independent of the EOF will be induced (siphoning effect). In theoretical considerations, a perfect plug-like flow is assumed. This assumption is not fulfilled in the case of siphoning effects. Siphoning effects can result in a dramatic decrease in efficiency. The same holds true for band broadening due to solute–wall interactions. Muijselaar et al.\(^29\) reported an intolerable decrease in efficiency when employing coated capillaries in MEKC. Band-broadening effects due to solute–wall interactions can also be due to fouling of the capillary.

3.6 Computer-assisted Resolution Optimization

Separations in MEKC are characterized by a large number of parameters and therefore empirical method development can be very difficult and time-consuming. Further complications can arise from the mutual interaction of these parameters affecting the separation. Computer-assisted resolution optimization schemes can be regarded as a tool in method development that gives guidelines for selecting the significant parameters, and that makes it possible to find suitable conditions after a minimum of initial experiments. Although for HPLC several optimization schemes have been published, these approaches at least require substantial modification before they can be used to optimize an MEKC separation.

An exhaustive and instructive introduction into this area was given by Khaledi et al.\(^59\) In a review by Corstjens et al.\(^60\) typical features of optimization
strategies applicable to MEKC are discussed. A more recent review on optimization strategies developed for MEKC was given by Khaledi.(8)

Approaches based on physicochemical models have to be distinguished from approaches based on empirical models. Although the use of physicochemical models is always preferred, since an in-depth understanding of the underlying equilibria can be achieved, such an approach is not always feasible, as numerous experiments can be required to determine the relevant constants in the equations with sufficient accuracy.

Smith and Khaledi(61) and Quang et al.(62) developed a strategy to model the migration behavior on the basis of physicochemical parameters estimated from model fitting on the basis of few initial experiments. With their approach, the rapid optimization of pH and surfactant concentration is possible. The linear relation between the retention factor and the concentration of surfactant [see Equation 18 and Figure 5] was used by Pyell and Bütehorn(24) to develop a strategy for the optimization of the surfactant concentration (one-parameter optimization) on the basis of only two initial experiments. This approach has been extended to the simultaneous optimization of the surfactant and the modifier concentration for urea(63) and acetonitrile(22) as modifier.

For certain parameters (e.g. temperature), physicochemical models are unavailable. In this case, empirical (also called statistical) models are useful in minimizing the number of experiments required to find suitable conditions. In addition to factor-based methods,(64) a simplex algorithm,(65) the overlapping resolution mapping scheme(66) and the iterative regression strategy(67) have been applied in MEKC. Wiedmer et al.(68) optimized the composition of a separation electrolyte containing SDS and SC by using empirical quadratic regression models.

3.7 Sample Stacking/Sweeping

Because of the small detection cell volume, which has to be chosen to avoid radial temperature gradient effects due to Joule heating (limitation of the inner diameter of the separation capillary) and to avoid extra-column band broadening (limitation of the length of the detection cell), MEKC methods often exhibit detection limits that are one or more orders of magnitude lower than in corresponding HPLC methods. The disadvantages due to the limitations of the detection volume, however, can possibly be overcome by on-line sample concentration techniques, which are not applicable in HPLC.

One on-line technique applicable in MEKC is stacking. Sample stacking was initially developed for charged analytes in CE. It is based on differences in the electric conductivity of bordering zones, resulting in differences in the effective migration mobilities \( \mu_e \) of the solutes, following from the Kohlrausch regulating function. If the sample solution has a conductivity much lower than that of the separation electrolyte, the electric field strength in the sample zone will be significantly higher than in other parts of the capillary. As the ions move across this boundary that separates regions of different electric field strength, they will be focused in a zone narrower than the initially injected sample zone. Sample stacking techniques developed for CE can be also applied for the MEKC separation of charged solutes.

According to Equation (9), a neutral compound also has a pseudoeffective mobility if \( k \) is different from zero. Hence sample stacking is possible with neutral solutes in MEKC, provided that the solutes exhibit an effective migration mobility \( \mu_e \) due to interaction with a pseudostationary phase during the stacking process.(69–72)

A second mechanism suitable for on-line concentration of neutral analytes in MEKC is sweeping. Sweeping is a term that was coined by Quirino and Terabe, defined as ‘the picking and accumulation of analytes by the pseudostationary phase that fills the sample zone during application of voltage’. It occurs whenever the sample matrix is devoid of pseudostationary phase and it does not need a lower electric conductivity in the sample solution than in the separation electrolyte. Sweeping can be compared to injection zone focusing processes occurring in conventional chromatography, when the sample solution is injected into the separation column. As has been shown by Quirino and Terabe,(73,74) in the reversed elution mode this concentration effect is effective, in particular, with solutes with very high retention factors. An on-line concentration effect that has been reported by Gilges(75) for the determination of impurities in a drug substance by MEKC in the normal elution mode is obviously also due to sweeping.

Theoretically, it should be possible to combine stacking and sweeping by preparing the sample in a solution with low electric conductivity containing no pseudostationary phase. The full potential of on-line concentration techniques in MEKC has not yet been pushed to its limit. On-line concentration techniques will play a key role in extending the applicability of MEKC to trace analysis and making this technique competitive in comparison with HPLC.

4 APPLICATION

4.1 Sample Preparation and Figures of Merit

There is no stationary phase in MEKC that can be fouled by irreversible sorption of matrix constituents, as the
separation electrolyte, containing the pseudostationary phase, is exchanged by rinsing procedures after each run. However, irreversible sorption of matrix constituents on the inner capillary wall must be avoided, as it results in an irreproducibility of migration times depending on the status of the capillary surface. In order to avoid blocking of the capillary by injected particles, samples should be filtered with a membrane filter prior to injection.

Because of the absence of a stationary phase and solubilization of matrix constituents by the micellar phase, direct sample injection is possible in many cases. In these cases, the highly efficient separation system must provide sufficient separation of the solutes of interest from interfering matrix constituents. In the case of direct sample injection of ‘dirty’ samples, often specific rinsing procedures between the runs have to be applied in order to maintain the repeatability of migration times.\(^{76}\)

With proper rinsing procedures and suitable thermostating of the capillary, the relative standard deviation of the retention times (intra-day) for detectable solutes in real samples is generally <1%.\(^{76–79}\) In practice, because of electrode reactions, buffer depletion can occur, resulting in a drift of the pH of the separation electrolyte and other parameters. This problem, however, can easily be overcome by a frequent change of the separation electrolyte. If the composition of the sample solution deviates strongly from that of the separation electrolyte (e.g. much higher content of organic modifier in the sample than in the separation electrolyte), peak splitting, retention time shifts and peak deformations (fronting, tailing, broadening) can result.\(^{(16,78,80)}\) Consequently, mismatch of the composition of the sample solution with the composition of the separation electrolyte has to be avoided or must be taken into account for the preparation of standard solutions.

In some publications, figures of merit obtainable with an HPLC method are compared with those that can be obtained with an MEKC method: determination of nitroaromatic compounds in soil,\(^{79}\) phospholipids in lecithin,\(^{81}\) phenolic compounds in spiritus liquor,\(^{77}\) impurities in a pharmaceutical compound\(^{75}\) and pesticides in aqueous matrix.\(^{82}\) In all these comparative studies photometric detection was employed. Although higher than those in HPLC, the limits of detection obtained in MEKC were fit for purpose.

Data obtained by HPLC agreed well with those given by MEKC.\(^{77,79,81}\) The precision of the determination expressed as relative standard deviation for the determined peak area is strongly dependent on the method parameters. With an internal standard (in order to eliminate imprecision in sample injection), relative standard deviations for the peak areas normalized on the peak area of an internal standard of <1% can be obtained.\(^{78}\)

With real samples (coffee, spiritus liquor) and suitable rinsing of the capillary between runs, relative standard deviations for the peak areas determined for consecutive runs (without internal standard) as low as 1–1.5% have been reported. In other studies, a significantly higher relative standard deviation for the (absolute) peak areas was obtained for the MEKC method in comparison with HPLC.\(^{(79,81)}\) However, the MEKC method can offer advantages over conventional HPLC methods in the routine analysis of real samples because of the higher peak capacity, higher efficiency and a selectivity different from that obtained in RPHPLC with conventional stationary phases: improved selectivity, higher accuracy due to baseline separation of adjacent peaks, separation of very closely related compounds (higher information content) and short run times.\(^{(75,81)}\)

### 4.2 Analysis of Drugs

Nishi and Terabe\(^{(83)}\) showed in a review on drug analysis by MEKC that most types of analysis in this field can be...
performed by using MEKC. These applications include purity testing of drugs, assay of drugs, determination of drugs in biological fluids, including the direct injection method, and separation of complex mixtures. Nishi and Terabe\(^83\) highlighted that MEKC is, in particular, a powerful method for the separation of complex mixtures such as natural products and crude drugs because of its high peak capacity.

MEKC with an ionic surfactant allows the direct injection of proteinaceous fluids, such as serum. Most of the work on the determination of drugs in biological fluids by MEKC with direct injection has been done so far with SDS as surfactant in the normal elution mode. The proteins are solubilized by SDS and elute (as a very broad band) after uric acid. With human serum or plasma, several drugs including theophylline\(^84\) (see Figure 8a and b) were shown to elute in an interference-free window in front of uric acid, allowing these substances to be analyzed by direct sample injection. It is also possible to analyze drugs in saliva and, in special cases, also in urine. An introduction to this very interesting field of application of MEKC has been given by Thormann.\(^85\)

Another important area of application of MEKC in drug analysis is direct enantiomer separations. These can be achieved either by employing chiral surfactants or with chiral additives to the separation electrolyte such as cyclodextrins in the presence of achiral micelles.\(^86\)

### 4.3 Analysis of Food and Beverages

In its present state, MEKC is not a routine method in food analysis. The methods in this field that have been developed so far, however, are very promising and show that MEKC can compete favorably with HPLC. The same advantages as outlined for the analysis of drugs by MEKC (high peak capacity, feasible direct injection,

short run times) hold true for the analysis of food and beverages.

Nouadjé et al.\(^ {87} \) were able to quantitate 28 biogenic amines and amino acids in red wines by MEKC with laser-induced fluorescence (LIF) detection of the fluorescein thiocarbamate derivatives (see Figure 9). Because of the high peak capacity in MEKC no clean-up steps were required. Bjervegaard et al.\(^ {88} \) developed an MEKC method for the determination of naturally occurring phenolic carboxylic acids (cinnamic and benzoic acid derivatives) in samples prepared directly from dietary fibers and other plant materials. According to Bjervegaard et al., the MEKC method developed is highly effective in comparison with HPLC and GC methods. Sűcs et al.\(^ {81} \) determined phospholipids in lecithins by MEKC with photometric detection and concluded that the MEKC method developed was preferable over the International Union of Pure and Applied Chemistry (IUPAC) HPLC method.

### 4.4 Miscellaneous

As most of the applications of MEKC reported so far are with photometric detection, there is a serious limitation on the applicability of MEKC to trace and ultratrace components in environmental samples. In spite of these limitations, the high peak capacity of MEKC methods can have advantages over conventional techniques in the analysis of very complex samples. Song et al.\(^ {89} \) reviewed the application of MEKC on the analysis of environmental pollutants.

In this context, methods to lower the detection limits are highly desirable. The following approaches are suitable for lowering detection limits in MEKC: on-line concentration (see section 3.7), off-line concentration during sample preparation and improving the sensitivity of detection. The sensitivity of detection can be improved by using detection cells with extended optical pathlength or by application of an alternative detection mode offering a better sensitivity than the conventional detection technique.

With suitable off-line concentration, MEKC can be employed for mono- and multiresidue analysis of herbicides in tap water at the micrograms per liter level.\(^ {90} \) Van Bruijnsvoort et al.\(^ {91} \) developed a method for the determination of chlorophenols by MEKC with amperometric detection. The detection limits obtained were of the order of \(10 \mu g \text{L}^{-1}\), one to three orders of magnitude lower than with photometric detection. Luong et al.\(^ {92} \) designed an off-column amperometric cell for the determination of explosives after detection by MEKC. Such a detection system offered a 10-fold detection limit improvement over photometric detection for most of the explosives tested. Penmetsa et al.\(^ {93} \) have shown that with proper precolumn derivatization techniques, LIF detection in combination with MEKC can provide detection limits for herbicides as low as \(10 \text{ng L}^{-1}\). Thermal lens detection can also offer advantages over photometric detection. Seidel et al.\(^ {94} \) employed MEKC for the separation of nitrophenol pesticides and obtained one to two orders of magnitude lower detection limits with thermal lens detection than with conventional photometric detection.

### 5 SEPARATION CARRIER CONCEPT

According to the separation carrier concept developed by Terabe,\(^ {7} \) MEKC is a special form of electrokinetic chromatography (EKC) when micelles are the pseudostationary phase. EKC is a technique that uses electrokinetic phenomena to perform a chromatographic separation. Hence in EKC, generally, charged and neutral solutes can be separated. A prerequisite of a chromatographic separation is a two-phase system, with phases of different migration velocity. This prerequisite can be fulfilled by adding a charged substance, that can incorporate solute molecules, to the separation electrolyte while performing CE. This charged substance, which can incorporate solute molecules, is usable as the ‘second phase’ (the ‘first phase’ is the surrounding bulk phase) in EKC. This ‘second phase’, migrating at a velocity different to that of the ‘first phase’, has been termed a separation carrier.

Not only surfactant micelles but also microemulsions, polymer ions, polymerized surfactants, dendrimers, resocarenes, charged cyclodextrins and other classes of substances, have been used as separation carriers in EKC. An overview of the different modes of EKC based on a classification of separation carriers was given by Nishi and Terabe\(^ {83} \) and Khaledi.\(^ {8} \) Charged cyclodextrins have found numerous applications in enantiomeric separations.\(^ {86} \) The interest in polymeric phases arises from the fact that they have a stable structure even when surrounded by a phase with a high content of organic solvent. The second advantage of these phases is the nonexistence of dissolved monomers at a concentration corresponding to the CMC of the surfactant. In EKC with an ionic surfactant (MEKC), these dissolved monomers increase considerably the specific conductivity of separation electrolytes.

However, considerations made for micelles as a separation carrier cannot always be directly transferred to the above-mentioned separation carriers. A constraint of Equation (2) and subsequent equations is the assumption that the velocity of the separation carrier is not altered by the incorporation of a solute molecule. At the present stage, it is not clear whether this constraint is fulfilled with all the separation carriers listed above.

1 Introduction

HPLC is one of the most popular and widely applied analytical techniques in use today. Among the many reasons for the technique’s popularity are its versatility and wide range of applicability. In its most common form, the modern analytical scale HPLC column has an internal diameter (ID) of 4.6 mm. However, the trend toward miniaturization common throughout analytical chemistry has led to the continued development of smaller diameter columns for HPLC. Today, HPLC in columns having diameters of less than 1.0 mm has evolved into a closely related family of techniques, collectively referred to as micro LC. These include open tubular (OT) LC (liquid
chromatography), packed capillary LC and microbore LC. Since the pioneering work of several research groups in the late 1960s and early 1970s, micro LC has grown into an important analytical technique offering several benefits over its conventional scale counterpart. Higher separation efficiencies, decreased analysis time, reduced solvent consumption and increased mass sensitivity are some of the advantages that have propelled the growth of this technique.

Owing to its high resolving power and quantitative capability, microscale LC is ideally suited to analyzing complex, volume-limited samples, for example the contents of individual biological cells. One limitation of micro LC imposed by the small column dimensions, however, is reduced sample loading capacity, which may result in decreased sensitivity relative to conventional LC.

CEC can be viewed as an outgrowth of micro LC. A relatively youthful technique, CEC represents a marriage of packed capillary LC and CE, a separation technique that itself has grown markedly since the early 1980s. In its most common form, CEC employs columns identical to those used in packed capillary LC (i.e. 50–250 µm ID fused silica capillaries packed with reversed-phase, silica-based particles). However, rather than using a pump to drive the mobile phase, bulk flow arises in CEC from electroosmosis, which is induced by an electric field applied across the capillary. For neutral species, the separation mechanism is identical to that in reversed-phase HPLC (i.e. partitioning between the mobile and stationary phases). Charged species, however, will be subject to electrophoresis as well as partitioning, providing a dual separation mechanism that may be employed to increase, or at least alter, selectivity. EOF is intrinsically advantageous for mobile phase propulsion in chromatography owing to its favorable flow dynamics, which result in decreased peak broadening relative to pressure-driven flow. This leads to much higher separation efficiencies in CEC than are obtainable in capillary LC. Higher efficiencies translate into greater resolving power. This combined with the advantages afforded by the small column dimensions (e.g. increased mass sensitivity, short analysis times, low sample volume requirement) make CEC an extremely powerful separation technique.

In contrast to packed capillary LC, the high efficiency of CEC affords high peak capacity, which is useful in analyzing mixtures containing many components. For this reason, CEC is especially suitable for analyzing highly complex samples, such as those involving biological or environmental matrices. As might be expected with a newly developed technique, a disadvantage of CEC is reproducibility.

2 HISTORY

2.1 Evolution of Microscale Liquid Chromatography

The development timeline of micro LC parallels that of “conventional” HPLC. Both were challenged and inspired by impressive achievements in the field of gas chromatography (GC). Technological developments in electronics and materials science, coupled with developments in theoretical descriptions of basic chromatographic processes, have driven both techniques toward increasingly better performance.

2.1.1 Semimicro High-performance Liquid Chromatography

The germ of HPLC was realized in 1941, when Martin and Synge published a classic paper in which they described liquid–liquid partition chromatography. They stated that in order to obtain fast separations, small particles and high pressures are required. Their suggestion was realized only in the late 1960s, after the pioneering work of Hamilton et al. in 1960 and Huber et al. in 1967. Most successes of GC such as pellicular and porous packing, temperature programming and especially the use of capillary columns (microbore columns in the present nomenclature) found immediate use in LC. Note that the term microbore as adopted here refers to columns of 1 mm ID. Several names have in the past been used for these columns, such as narrow bore, microbore and small-bore. The various sizes and nomenclature of HPLC columns are presented in the flow chart depicted in Figure 1.

A number of papers published in the late 1960s considered the use of high-pressure LC in the microscale format, primarily with columns having IDs of 1 and 2 mm. Horvath et al. published the first microbore HPLC chromatogram in 1967, which illustrated the use of pellicular packing for the separation of ribonucleoside–monophosphoric acids in about 30 min.

In 1969 Kirkland reiterated the feasibility of the technique by separating urea herbicides in less than 6 min with a 2.0 mm ID column. In 1979 Scott and Kucera showed experimentally that very high theoretical plate numbers (750 000) could be achieved with a microbore column. Five years later, Menet, Gareil and Rosset announced that efficiencies as high as one million plates could be obtained by using a 22 m long microbore column operated at 800 bar inlet pressure.

The “high speed” expectation has already been met. Likewise, other advantages of microbore columns such as good resolution, minimal sample volume and low solvent consumption have been realized. In fact, for a while the
term high-pressure or high-speed LC was synonymous with microbore LC.

In 1970 DeStefano and Beachell\(^\text{10}\) used columns with larger diameters (8–11 mm) and achieved efficiencies that at the time were better than those obtained with microcolumns. The improvement is caused by the so-called “infinite diameter effect” that occurs when a sample is injected centrally into a wide column. The result is a decrease in band broadening since the “wall effects” due to permeability inhomogeneity across the column are diminished. Since then wider bore columns have been the preference and have come to be the convention in HPLC.
2.1.2 Open Tubular High-performance Liquid Chromatography

The first LC separation in an OT column was obtained in 1970. A soft glass capillary of 0.23–0.30 mm ID was treated with alkaline solution to generate a silica gel layer and then used to separate dansyl amino acids. Because of the large column diameter, the resolution was poor and the separation required 5 h. Tsuda and Novotny published in 1978 their analysis of band broadening phenomena for unretained species indicating the potential for high-resolution separations with open tubular liquid chromatography (OTLC). In 1978 Ishii applied the results of earlier theoretical studies, which indicated that smaller IDs provide higher efficiencies, and used a microcapillary tube of 60 μm ID. He demonstrated that both physically coated and chemically bonded stationary phases were able to resolve the components of a mixture by LC.

The high efficiency attainable in OTLC was demonstrated by the achievement of 2800000 theoretical plates with a 27.5 m long column of 32 μm ID.

For OT capillary columns, large numbers of theoretical plates (>250 000) are not unusual in GC and over the years it has been proven that efficiencies such as this could also be achieved in LC. OT columns have the highest permeability of all column formats, allowing them to produce larger numbers of theoretical plates per unit time and unit pressure drop than packed columns (PCs).

Skill and experience are necessary to obtain OT columns with a uniform stationary phase layer. Covalent bonding of the stationary phase on the walls of the column offered a more uniform and stable coating, which made solvent gradient elution and temperature programming possible. On the other hand, the covalently bonded stationary phase consists of a monomolecular layer having inherently low-analyte capacity; unfortunately OT columns usually require a high-loading capacity to achieve adequate detection limits (DLs).

To achieve maximum efficiency in OTLC requires the use of narrow ID columns, typically 10 μm and below. Peak volumes generated in columns of this size are on the order of 0.1 nL and were incompatible with the detectors available at that time owing to excessive extra-column peak broadening. Unfortunately, this issue limited the use of such columns.

Approaches to increase the sample capacity of the column involved the use of support materials coated on the walls of the capillaries. Supports such as silica gel, porous silica microspheres or organic polymers (polystyrene, polyacrylates) were studied.

The development of fused silica capillary columns in 1979 by Dandeneau and Zerenner revolutionized miniaturized separation techniques. As opposed to the fragile glass columns and surface inhomogeneities of metal columns, the surface of fused silica is smooth, more inert, and the outside polyimide coating makes it flexible and much easier to work with. Before long, fused silica became the material of choice in both the OT and packed capillary format.

The first to investigate LC in fused silica capillaries was Frank Yang, who derivatized columns of different IDs with octadecylsiloxane. The best results were obtained with the 30 μm ID capillary. In the same paper he introduced in situ or on-column detection, which could easily be performed after removing the polyimide coating from a small section of the capillary (2–10 mm). This design effectively eliminated any extra-column volume contribution from the detection cell.

The challenge posed by microbiology on the practical limits of microanalysis drove forward the development of detection systems, such that even smaller ID columns might be used. Their manufacture was not an easy task. In 1988 fused silica capillaries of 2 μm ID were obtained, but the high purity intrinsic to fused silica makes it extremely difficult to increase its surface area by etching in order to enhance column loadability. Therefore, materials used early in the development of LC, such as soda lime glass or borosilicate glass, were etched with acidic and basic solutions to give higher inner surface areas. Subsequent chemical bonding of the stationary phases provided the desired selectivity of the OT column.

The requirement of highly specialized instrumentation derived from the limited column loadability narrows the applicability of OTLC.

2.1.3 Drawn-packed Capillaries

An interesting alternative solution to the small loadability of OT columns and high-flow resistance parameters of PCs is offered by drawn-packed microcapillary columns, also known as semi-packed microcapillary columns.

These columns were widely used in GC. In 1978 Tsuda and Novotny achieved the first liquid-phase separations in drawn-PCs of 50–200 μm ID, ten times smaller than those currently used in GC. The manufacturing process consists of packing 1–2 mm ID tubing with sorbent material and subsequently drawing it to the desired diameter using a glass drawing machine. The application of high temperatures during the drawing process results in the impression of some packing material on the walls of the tubing conferring the “loose” packing structure specific to this type of column. Unfortunately, such high temperatures preclude the use of derivatized packing materials. Nevertheless, it is possible to prepare various chemically bonded stationary phases in situ, by passing the silane reagent through the capillary. Efficient separations were obtained with a 42 μm ID column of 29.4 m length. Theoretical plate
numbers varied from 400 000 to 880 000 but the analysis required more than 3 h.

2.1.4 Micropacked Capillaries

The low sample capacity of OT columns encouraged scientists to return to the study of PCs for LC. Interestingly, the packed capillary column format actually minimizes the previously described “wall effects”. For a certain particle diameter, as the walls of the capillary are closer together the overall permeability across the column is more homogeneous.\(^26,27\) This results in a decreased range of flow velocities, smaller pressure drop and more effective dissipation of the frictional heat generated in the column. Thus, in contrast to conventional columns, micropacked capillaries facilitate the use of longer columns, resulting in higher theoretical plate numbers. However, some of the problems encountered with narrow bore columns (such as extra column effects and difficulties in obtaining uniform packing) had to be addressed.

In 1979 Scott and Kucera introduced a low-dead-volume detection cell of 1 µL, which significantly improved detection sensitivity.\(^28\) Numerous other geometries were proposed, but on-column detection remains the most popular for fused silica capillaries in spite of the path length limitation it imposes.

In 1969 Knox and Parcher studied the interrelationship between column ID, particle size and plate height.\(^29\) The research, continued by Wilson and McNair\(^29\) for capillary columns, indicated that higher efficiencies can be obtained for Knox–Parcher ratios \(\rho\), defined as the column diameter divided by the diameter of the packing material, of less than five because they generate a more ordered packing structure.

In addition to the general trend toward smaller diameter particles, the design of the packing material itself was continually improved with respect to uniformity in particle and pore sizes. From the small glass spheres coated with a layer of silica gel or microspheres of silica\(^7\) to the present day material (porous homogeneous covalently bonded microparticles of 2–10 µm), the evolution of packing materials has led to increased column efficiencies. However, conventional (4.6 mm ID) columns packed with the smaller size particles develop an extremely large pressure drop. Capillary columns present one practical solution to this problem. Efficiencies of 100 000 theoretical plates can routinely be attained when columns of 1 m length containing 3 or 5-µm particles are used.\(^30\)

Column packing was extensively studied and methods such as balanced density slurry and vacuum pulled slurry were commonly used.\(^4\) In the first procedure the packing material was mixed with a solvent of similar density (tetrachloromethane), such that the slurry obtained was less susceptible to aggregate formation during packing. High pressures (700–1000 bar) were used to force the slurry into the capillary, the result being a homogeneous, well-packed chromatographic bed. For glass, PTFE (polytetrafluoroethylene) and other tubing materials that could not withstand such high pressures, the packing method proposed by Ishii,\(^31\) which used vacuum to pull the slurry into the capillary, was appropriate. After packing, a compression step was required to compact the bed.

The flexibility of fused silica and availability of polymeric ferrules that permit high-pressure operation greatly facilitated the development of improved packing techniques. Novotny et al. modified the slurry packing method by using higher density slurries, which were sonicated during packing to maintain homogeneity. A less viscous solvent (acetonitrile) was used as both slurry and displacement fluid.\(^30\) The use of acetonitrile also decreased the time required to pack and depressurize the column. It must be stressed that the optimum slurry and/or displacement solvent may vary with packing materials which have different surface chemistries.

Considering the performance of micropacked capillaries coupled with the versatility of the packing materials already available for conventional LC, it is widely considered that the micropacked capillary format of micro LC has the greatest potential for continued development and application.

2.2 Capillary Electrophoresis and Its Influence on Microscale Liquid Chromatography

As early as 1877, Helmholtz studied the effect of the application of an electric field across a glass capillary filled with a salt solution.\(^32\) He determined that the wall of the capillary acquired a negative charge, and that while voltage was applied, positively charged particles associated with the wall moved toward the cathode. This nondiscriminatory transport process was termed electroosmosis or electroendosmosis.

The movement of charged particles in solutions under the influence of an electric field, the other electric-field driven transport mechanism, called electrophoresis, was intensively studied by electrochemists. Not until 1937 did electrophoretic migration catch the interest of a separation scientist. Tiselius exploited the differences in electrophoretic mobilities of proteins to separate them, and UV (ultraviolet) photography to detect them.\(^33\) In these studies, it soon became obvious that resistive heating of the solution caused severe band broadening and the appended cooling systems could not effectively eliminate the problem. In spite of this limitation, several separation techniques, including free zone electrophoresis, isotachophoresis, isoelectric focusing, all of which are
based on electrophoretic transport, have become important analytical tools, especially in the fields of biology and biochemistry.

Column miniaturization became fashionable in the early 1960s and with good reason. In 1970 Hjerten introduced surface coating of the walls of small capillaries to minimize electroosmosis, which resulted in essentially pure electrophoretic migration of species. The benefits introduced by column downsizing, such as increased heat dissipation, sensitive real-time detection, applicability to samples in limited amount and ease of automation were notable. The significant increase in efficiency revealed in 1981 by Jorgenson and Lukacs provided a major breakthrough in the field of electrophoresis.

A term was required for the new technique and CE was an obvious choice. The ever-increasing number of practical applications that span from small organic and inorganic molecules, to bio and synthetic polymers, drugs, food additives, and so on, established the name “high-performance CE”.

Before long, several other variations of CE were developed. Some of the methods that stemmed from CE adopted the electric-field driven migration of the sample and solvents as a bulk transport mechanism. This is the point at which CE, which owed its rapid progress to the ready application of available chromatography advances, began to reward its predecessor.

2.3 Crossroads of Capillary Electrophoresis and Liquid Chromatography: Micellar Electrokinetic Capillary Chromatography and Capillary Electrochromatography

In 1984 Terabe et al. proposed an interesting separation technique which he referred to as micellar electrokinetic capillary chromatography (MEKC). In this technique an anionic surfactant (SDS (sodium dodecyl sulfate) is widely used) is added to the buffer of the CE system at a concentration higher than its critical micelle concentration, such that it forms transient micelles. During a run the neutral components of the sample move towards the cathode carried by the EOF. Given the negative charge of the micelles, the direction of electrophoretic migration is toward the anode. However, in uncoated capillaries the magnitude of the EOF vector is usually larger than the electrophoretic component of the micelle. Therefore, the micelles migrate toward the cathode, although at a lower speed than the bulk solution. If an analyte partitions into the micelle, it moves during the period of association at the micelle velocity. Different affinities for the micelles, hence different partition coefficients into the “pseudostationary phase” allow for the separation to occur. Thus, MEKC is a chromatographic technique because the separation mechanism is based on distribution equilibria.

Although the invention of MEKC greatly widened the applicability of CE, it did not broaden the technique to the point of universal utility. Analysts that partition into the micelles are sparingly soluble in water and only small amounts of organic modifiers could be added to enhance solubility without perturbing the formation of micelles. Techniques that allow the use of high concentrations of organic solvents would perhaps be more versatile.

In 1974 Pretorius et al. studied electroosmosis in packed glass tubes and observed that irregularity in the packed bed did not affect the chromatographic performance. High efficiencies were obtained for unretained species, indicating the potential of the technique. In 1981, Jorgenson and Lukacs replaced the high-pressure pump of micro LC with EOF in 170-µm-ID, 68-cm long capillaries packed with 10-µm reversed-phase particles. The column generated over 20 000 theoretical plates corresponding to reduced plate heights of 1.9 and 2.5. At the time, the typical optimum reduced plate height for PCs was 2.5, so these values demonstrate the potential for ultrahigh efficiencies for electro-driven separation techniques. This application of electroosmosis for bulk transport in micro LC would later be called CEC.

In 1988, Knox described the theory of CEC operation, but the method was not widely researched before a new paper was published in 1991. There, Knox employed both slurry packed capillaries and drawn-packed capillaries in a comprehensive study of the effect of particle size on EOF velocity. He found that particle size had essentially no effect on velocity and electrolyte concentration as low as 0.002 M resulted in a relatively fast analysis with high efficiency. An impressive 500 000 plates m⁻¹ and reduced plate heights of 1.3 were obtained for the slurry PC.

3 THEORY

3.1 Efficiency and Its Effect on Resolution in Chromatography

In LC, separation is achieved by the differential migration of solutes through the column, which arises due to the solutes’ partitioning behavior between the stationary phase and flowing solvent (mobile phase). The quantitative measure of the separation of any two components is resolution ($R_s$). Resolution is an important chromatographic feature of merit because it is a measure of the ability of the system to distinguish between closely spaced components in a separation. The goal in chromatography is to obtain adequate resolution of the components of interest in a minimum amount of time.
Separations in which many components must be resolved are often the most challenging. This is typically the case when the species to be analyzed are present in a complex matrix. To obtain adequate separations with these samples generally requires high resolution. To meet these challenges, there is an ever-present need to seek ways in which chromatographic resolution can be maximized while at the same time minimizing analysis time.

The master resolution equation expresses resolution as a function of three basic chromatographic parameters: capacity factor, selectivity and efficiency

\[ R_s = \frac{1}{4} \left( \frac{k^2 - 1}{1 + k^2} \right) \left( \frac{a - 1}{a} \right) \sqrt{N} \]  

(1)

The first term in Equation (1) is capacity factor \((k')\) dependent. The capacity factor for a given solute is a measure of its affinity for the stationary phase (it is proportional to the solute’s thermodynamic partition ratio). If all other variables are held constant, a solute with a lower value of \(k'\) will migrate through the column faster (i.e. have a shorter retention time) than a solute with a greater \(k'\).

The second term in the equation is selectivity, or separation factor, \((\alpha)\) dependent. Selectivity, which is measured for a pair of peaks, is simply the ratio of their capacity factors. Selectivity values are by definition greater than or equal to one and indicate differences in the affinities of analytes for the stationary phase. Capacity factor and selectivity are dependent upon the thermodynamics of the solute–stationary phase interaction.

The third term in the master resolution equation is efficiency \((N)\) dependent. Efficiency is related to the narrowness of the chromatographic peak and is expressed as the number of theoretical plates. Unlike capacity factor and selectivity, efficiency is chiefly affected by physical, rather than chemical processes that occur as the solute passes through the column. These processes include kinetic phenomena such as molecular diffusion, slow mass transfer and others that result in broadening of peaks as they migrate through the column. Efficiency is quantified by Equation (2):

\[ N = \frac{t^2}{\sigma^2} \cong 16 \left( \frac{t_r}{W_b} \right)^2 \]  

(2)

where \(t_r\) is the retention time of the peak, \(\sigma^2\) is the peak variance (the square of the standard deviation \(\sigma\)) in units of time and \(W_b\) is the peak width at baseline in time units.

From Equations (1) and (2) it is evident that peak broadening degrades resolution. It is desirable, then, to minimize peak broadening by understanding and minimizing (as much as it is possible) its causes.

A more useful parameter with which to assess chromatographic peak dispersion is the height equivalent to a theoretical plate or plate height \((H)\), which is given by Equation (3):

\[ H = \frac{\sigma^2}{L/N} = \frac{L}{N} \]  

(3)

where \(\sigma^2\) is the peak variance and \(L\) is the column length. Plate height is a measure of peak broadening per unit column length. Assuming Gaussian peaks, which under most conditions is a reasonably valid assumption, plate height may be viewed as the length of column that “contains” one theoretical plate (Equation 3).

Greater values of \(H\) correspond to broader peaks. Because peak height is a measure of peak broadening per unit length of column, it is often a more useful feature of merit than \(N\) in that it allows direct comparisons between columns of different lengths. In PC chromatography, plate height is often expressed in its reduced form, \(h\), \((h = H/d_p)\) in which it is normalized to the packing particle diameter \((d_p)\).

Let us now examine the phenomena that contribute to \(H\). According to chromatographic rate theory, peak broadening arises from various kinetic factors that occur as the solute zone passes through the column. The following well-known relationship, which derives from chromatographic rate theory, expresses plate height as the sum of individual contributions, Equation (4):

\[ H = A + \frac{B}{\mu} + C_s\mu + C_m\mu \]  

(4)

In this general form of the equation, the \(A\) term represents the plate height contribution due to eddy diffusion and the \(B\) term represents axial molecular diffusion. The contributions of slow solute mass transfer in the stationary and mobile phases are contained in the \(C_s\) and \(C_m\) terms, respectively. Mobile phase linear velocity is given by \(\mu\). It is common in chromatography to depict the dependence of \(H\) on \(\mu\) graphically in the form of a Van Deemter plot.

The eddy diffusion or \(A\) term in Equation (5) arises primarily from the multiple pathways in a packed bed through which solute molecules can flow. A molecule traveling a less tortuous path will travel faster relative to the average condition. Conversely, a molecule traveling in a more difficult path will fall behind with respect to the average. The resultant chromatographic peak, a distribution of arrival times about a mean value (the peak apex), becomes broadened. It has been shown that the magnitude of the \(A\) term is proportional to the diameter of the packing particle:

\[ A \propto d_p \]  

(5)

Axial, or longitudinal molecular diffusion, represented by the \(B\) term, is the plate height contribution caused
by diffusion of solute molecules along the column axis. The $B$ coefficient is proportional to the solute’s diffusion coefficient in the mobile phase. The slower the velocity of the solute zone through the column, the more time is available for diffusion to occur, thus there is an inverse relationship between mobile phase velocity and the magnitude of this contribution. In liquids, the diffusion coefficients of solutes are small (typically on the order of $10^{-5} \text{ cm}^2 \text{s}^{-1}$). For this reason, the effect of axial diffusion on peak shape is minimal under typical operating conditions.

A finite amount of time is required for solute molecules to enter and leave the stationary phase. The rate of this exchange has an inverse effect on column efficiency (slower exchange results in broader peaks). The $C_s$ term of the plate height equation represents this contribution to plate height. As might be expected, the value of $C_s$ is related to the thickness of the stationary phase layer on the particle surface. In modern LC, the stationary phase film is typically formed as a monolayer on the particle surface. Because of this, slow mass transfer in the stationary phase is usually a minor contributor to plate height.

The contribution to plate height of slow mass transfer kinetics in the mobile phase is included in the $C_m$ term. In even the most well packed LC column, point to point differences in mobile phase velocity exist. For example, velocity differences arise from the intrinsic nature of laminar (pressure-driven) flow. Consider for instance that in any microscopic flow channel within the packed bed (e.g. in the packing interstices), the flow velocity is at some maximum value at the channel center and zero at the particle surface. Between these extremes, flow velocity varies as a function of distance from the center. Molecules near the center of the channel will outdistance those near the particle surface, broadening the zone. Diffusion of solute molecules into and out of the various velocity regimes serves to counteract the zone broadening effect. However, as discussed above, diffusion coefficients in liquids are small and so this velocity nonhomogeneity effect contributes to plate height. Slow solute diffusion in the mobile phase results in additional zone broadening effects when porous packings are employed. Stagnant mobile phase mass transfer involves pools of nonflowing mobile phase deep inside the pores of the packing material. Solute molecules that diffuse into these pools fall behind with respect to the average and the peak broadens. Because diffusion is the sole mechanism by which solute molecules enter and leave the pools, the slow diffusion rates of solutes in liquids exacerbate zone broadening due to this process.

Not surprisingly, the $C_m$ term scales in inverse proportion to the solute’s diffusion coefficient in the mobile phase ($D_m$). The proportionality in Equation (6) shows the dependence of $C_m$ on particle size and the diffusion coefficient:

$$C_m \propto \frac{d_p^2}{D_m} \quad (6)$$

### 3.2 Advantages of Column Miniaturization

The ongoing evolution of HPLC has led to the development of ever-smaller column diameters (<1.0 mm) since the mid 1980s. The impetus for this miniaturization has been the numerous advantages afforded by miniaturized columns. These advantages include:

- improved column permeability, resulting in enhanced efficiency
- decreased solvent consumption
- increased mass sensitivity
- more efficient heat transfer
- less packing material required
- more facile interfacing with mass spectrometry (MS).

Let us now examine each of these advantages in greater detail.

#### 3.2.1 Column Permeability

The permeability of a chromatographic column is a measure of its resistance to flow and is related to the dimensionless flow resistance parameter $\phi$, Equation (7):

$$\phi = \frac{\Delta P d_p^2}{\mu L \eta} \quad (7)$$

where $\Delta P$ is the pressure drop, $d_p$ is the particle diameter, $L$ is the column length, $\eta$ is the mobile phase viscosity and $\mu$ is the mobile phase linear velocity. Rearrangement of Equation (7) shows a direct proportionality between $\Delta P$ and $\phi$. With a fixed set of operational conditions (i.e. fixed $d_p$, $L$ and $\eta$), the pressure drop required to obtain a particular linear velocity is dependent upon $\phi$. This is relevant in LC because there is an upper limit to the pressure attainable by conventional instrumentation (usually no higher than 400 bar). This in turn places limits on $L$ and $d_p$, which affect efficiency, and $\mu$, which affects analysis time. Within these limits, optimizing the separation usually involves a compromise between efficiency and speed.

A useful parameter in assessing the performance characteristics of LC columns that incorporates pressure drop and analysis time is separation impedance ($E'$). This dimensionless parameter introduced by Bristow and Knox is a measure of column efficiency per unit time and per unit pressure drop, and is defined by Equation (8):

$$E' = \left( \frac{t_0}{N} \right) \left( \frac{\Delta P}{N} \right) \left( \frac{1}{\eta} \right) = \left( \frac{H}{d_p^2} \right) \phi \quad (8)$$
where \( t_0 \) is the elution time of an unretained solute; other variables are defined previously. Lower values of \( E^\dagger \) correspond to better column performance. Values of \( E^\dagger \) and \( \phi \) for various column diameters are shown in Table 1. The lower \( E^\dagger \) values of miniaturized columns mean that these columns can yield more theoretical plates in less time and with a lower pressure drop relative to conventional bores.

The enhanced permeability of miniaturized columns allows for further increases in efficiency by making possible the use of smaller packing particles and/or longer columns. Recall from Equations (4–6) that plate height is related to particle size through the \( A \) and \( C_m \) terms of the plate height equation and efficiency is proportional to column length (Equation 3). In spite of this, conventional columns are constrained by excessive pressure drop, which limits usable lengths and particle sizes. Most 4.6-mm columns are 150–250 mm long and employ 5 \( \mu \)m particles. Alternatively, the use of smaller particles can result in reduced analysis times because when particle size is reduced, a given plate number is achievable with a shorter length of column.

### 3.2.2 Solvent Consumption

Decreasing column diameter results in a substantial reduction in the volumetric flow rate required for a given linear velocity. Volumetric flow rate (\( F \)) through a PC is given by Equation (9):

\[
F = \frac{\pi d_c^2 \varepsilon_{\text{tot}} \mu}{4}
\]

where \( d_c \) is the column diameter and \( \varepsilon_{\text{tot}} \) is the total column porosity. The dependence of \( F \) on the square of column diameter translates into significant reductions in solvent consumption on miniaturization. Table 2 compares volumetric flow rates for various column diameters. For example, downsizing to a 1.0-mm ID from a conventional 4.6 mm will reduce solvent consumption over 20-fold. Decreased solvent consumption is economical (reduced purchase and disposal costs) as well as environmentally responsible.

#### 3.2.3 Mass Sensitivity

Chromatographic separations are intrinsically processes of dilution: an initial sample plug of concentration \( C \) is diluted in the mobile phase and reaches the detector as concentration \( C' \) (where \( C' < C \)). Because the majority of LC detectors are concentration-based, a reduction in sensitivity results. To understand why this process is ameliorated upon column miniaturization, we will define peak volume (\( V_p \)). Assuming a Gaussian peak, Equation (10):

\[
V_p = F W_b = \left( \frac{\mu \varepsilon_{\text{tot}} \pi d_c^2}{4} \right) W_b
\]

where \( W_b \) is the peak width at baseline in units of time. \( V_p \) is simply the volume over which the peak elutes. According to Equation (10), peak volumes are proportional to the square of column diameter; thus values of \( V_p \) for microcolumns are substantially smaller than for conventional 4.6-mm columns.

The concentration of solute at the peak maximum is inversely proportional to \( V_p \). Qualitatively, this relationship can be envisioned as follows. A given mass of solute is diluted in a volume \( V_p \), yielding a concentration \( C \). If the same mass is diluted in a smaller volume \( V'_p \), the resulting concentration \( C' \) will exceed \( C \) in proportion to the volume difference. As indicated in Table 3, for a fixed mass of solute injected, column miniaturization can result in substantial increases in sensitivity with concentration-based detectors (e.g. UV, fluorescence).

#### 3.2.4 Other Advantages

Decreased cross-sectional area allows for more efficient heat transfer to and from the column interior. Relative to conventional bore columns, miniaturized columns are capable of more rapid equilibration at different temperatures, which makes possible the use of temperature

programming as in capillary GC. In addition, these columns can more effectively dissipate heat generated by the pressure drop, minimizing temperature gradients that can cause peak broadening. Smaller volume columns require less packing material, which is beneficial if costly “exotic” materials are used. This is also the case for mobile phases.

The low volumetric flow rates of miniaturized columns simplify interfacing to MS. Columns may be interfaced directly using thermospray, electrospray and other means, obviating the need for flow splitting, which reduces sensitivity.

### 3.3 Extra-column Effects

Not all peak broadening occurs within the chromatographic column. In addition to the phenomena accounted for in the plate height equation (Equation 5), which occur as the solute band passes through the column, the final peak width is affected by so-called extra-column effects. These include contributions from the sample injector, the injection volume, connecting tubing, detector cell volume and the detector time constant. Well-designed chromatographs are constructed such that extra-column effects comprise a small fraction (≤10%) of the final peak width. One disadvantage of column miniaturization is that the system becomes more susceptible to extra-column effects as column diameter decreases.

Peak volume \( V_p \) was defined in Equation (10) as the peak width at baseline in units of volume. For Gaussian peaks, the final peak volume observed at the detector \( V_{obs} \) can be expressed in terms of the in-column \( V_p \) and extra-column \( V_{ec} \) contributions, Equation (11):

\[
(V_{obs})^2 = (V_p)^2 + (V_{ec})^2
\]

Dividing through by \( V_p^2 \) gives the relative increase in \( V_{obs} \) from extra-column effects, Equation (12):

\[
\left( \frac{V_{obs}}{V_p} \right)^2 = 1 + \left( \frac{V_{ec}}{V_p} \right)^2
\]

According to this equation, if the extra-column contribution to the final peak volume, \( V_{obs} \), is to be limited to 10%, then the extra-column volume must not exceed 46% of the column peak volume. This poses less of a problem with the relatively large peak volumes encountered with conventional bore columns. However, because peak volumes are proportional to the square of column diameter, to maintain the same fraction (10%) of extra-column broadening in micro LC requires much more stringent control of extra-column volumes. In such cases, extra-column volumes must be significantly reduced in order to minimize the contribution to the final peak volume. As a consequence, conventional HPLC instrumentation (i.e., injector, tubing and detector) must be modified in order to accommodate smaller diameter columns, which is a disadvantage of micro LC. Table 4 lists maximum allowable values for injection volume, connecting tubing length and detector cell volume for various column diameters.

In addition to the dilution and mixing that occurs within extra-column volumes, a contribution to band broadening may arise from the detection electronics. The speed with which the detector responds to a change in

Assumed conditions: \( \epsilon_{tot} = 0.7 \); \( \mu = 2.0 \text{ mm s}^{-1} \); \( N = 10000 \); \( L = 250 \text{ mm} \); \( k' = 2 \); \( D_m = 10^{-5} \text{ cm}^2 \text{s}^{-1} \).

a Allows 5% peak broadening.
b Allows 3% peak broadening, connective tubing diameter = 250μm.
c Allows 3% peak broadening, connective tubing diameter = 50μm.
d Assumes on-column detection with a negligible extra-column volume contribution.
solute concentration is affected by its time constant, $\tau$. The time constant, which typically can be adjusted within a range of values, is useful as a filter for high-frequency noise in the chromatogram. Longer time constants slow the detector response providing enhanced signal filtering. Problems arise when the chromatographic peaks are very narrow, as in high efficiency separations. In these cases, slow detector response (long time constants) will result in additional peak broadening. It can be shown\(^\text{[43]}\) that the maximum allowable time constant for a given fraction of peak broadening is proportional to $1/\sqrt{N}$. Thus, detectors employed in high efficiency separations require more rapid detection electronics.

### 3.4 Flow Profile and Efficiency: Advantages of Electro-osmotic Flow

EOF originates near the fused-silica capillary wall (or packing particle surface) owing to a charge imbalance that exists at the surface–liquid interface. The surfaces of fused-silica tubing and silica-based packing materials bear a net negative charge owing to the presence of ionized silanol moieties (Si–O\(^-\)). When exposed to a solution containing oppositely charged ions (e.g. the mobile phase), the surface will attract counterions to preserve electroneutrality. The attracted counterions form a two-part layer at the surface, known as an electrical double layer. The Stern layer consists of immobile counterions tightly affixed to the surface. A second layer, the Gouy or diffuse layer, extends some distance from the surface. The counterions present in this diffuse region are mobile and freely exchange with counterions in the bulk solution. The electrical double layer is depicted in Figure 2. Upon application of an electric field, counterions in the diffuse region begin to migrate toward the electrode of opposite polarity (generally the cathode). Because these migrating ions are solvated and because of frictional forces, the bulk solution is dragged toward the respective electrode. Electroosmosis is particularly advantageous as a driving force for mobile phase flow in chromatography because it generates considerably less peak broadening relative to pressure-driven flow. This is mainly because of the more uniform velocity profile of EOF. In fact, the potential to combine the selectivity of HPLC with the favorable flow dynamics of electroosmosis has been a driving force in the development of CEC. There are three main advantages of EOF over pressure-driven flow for mobile phase propulsion in chromatography: (1) EOF flow velocity is radially uniform (across flow channel), (2) EOF flow velocity is independent of channel diameter, and (3) EOF requires no pressure drop. Let us explore each of these points in greater detail.

Consider a capillary tube of radius $r_c$. In pressure-driven (or laminar) flow, the flow velocity at any radial point in the tube $u(r)$ is a function of distance from the center as given by the Hagen–Poiseuille Equation (13):

$$u(r) = \frac{\Delta P}{4\eta L}(r_c^2 - r)$$

where $r$ is the distance from the tube center. The resultant flow velocity profile is parabolic in shape. There exists a distribution of velocities over the tube cross-section. Recall from the discussion of the mobile phase mass transfer contribution to plate height (section 3.1), that such velocity inhomogeneity leads to an increase in plate height. More specifically, this zone-broadening phenomenon is known as the transchannel effect.\(^\text{[44]}\)

Consider now EOF through the same capillary tube. EOF velocity $\langle v_{eo} \rangle$ at any radial point in the tube is given by Equation (14):

$$\langle v_{eo} \rangle = \frac{\varepsilon \xi E}{4\pi \eta} \left( 1 - \frac{I_0(k_d a)}{I_0(k_d \xi \eta)} \right)$$

where $\varepsilon$ is the permittivity of mobile phase, $\xi$ is the zeta potential, $E$ is the electric field strength, $\eta$ is the mobile phase viscosity, $k_d$ is the reciprocal of the thickness of the double layer, $a$ is the distance from the center of the tube and $I_0$ is a zero-order Bessel function of the first kind.

Typically, the double layer thickness is quite small (on the order of 1 nm) and the term in parentheses reduces to one, yielding the following expression, Equation (15):

$$\langle v_{eo} \rangle = -\frac{\varepsilon \xi E}{4\pi \eta}$$

where $\langle v_{eo} \rangle$ indicates the average flow velocity in the tube. Equation (15), which is valid in the absence of double-layer overlap, shows that EOF velocity is independent of radial position in the flow channel. Thus, the flow profile is flat over most of the capillary cross-section. Figure 3.
compares the radial profiles of pressure and electrically driven flow. This uniformity in flow velocity minimizes transchannel zone broadening, resulting in a lower $C_m$ term in the plate height equation.

In packed chromatographic columns, there invariably exist local differences in packing density which give rise to interstitial flow channels of varying diameter. With pressure-driven flow, the squared dependence of velocity on channel diameter (Equation 13) gives rise to a distribution of velocities in these channels. As in the transchannel effect discussed previously, point to point differences in flow velocity contribute to zone broadening. The plate height increment due to this phenomenon is part of the eddy diffusion ($A$) term of the plate height equation.

In contrast, EOF velocity, which is essentially independent of channel diameter, results in a much more uniform distribution of velocities in spite of differences in local packing density (depicted in Figure 4). We can expect the improved velocity distribution of electrically driven flow to result in a lower $A$ term in the plate height equation.

The third advantage of EOF is that no pressure drop is required. This is important from the standpoint of efficiency because it permits the use of smaller diameter particles. Plate height, as discussed in section 3.1, is strongly dependent upon particle diameter and decreases with a decrease in $d_p$. In HPLC this advantage is offset by the inverse square dependence of pressure drop on $d_p$ (Equation 7). The maximum pressure attainable by most commercial LC pumps is about 400 bar, which in most cases limits particle diameter to not less than 3 µm. With no such limit, CEC separations regularly employ 1.5-µm particles and the potential exists to employ much smaller particles.[45]

Reduced plate height values obtained for the same columns under electrically and pressure-driven conditions have been shown to be consistently lower under the former,[59] a direct result of the improved flow dynamics of EOF. Greater efficiency, combined with the absence of pressure drop gives CEC the potential to generate total column plate numbers that are substantially higher than micro HPLC.

<sup>a</sup> Column length limited to 35 cm owing to high-pressure limit.

<sup>b</sup> Column length limited to 9 cm owing to high-pressure limit.

Assumed conditions: linear velocity = 1.0 mm s<sup>-1</sup>; column length = 50 cm; high-pressure limit (micro LC) = 400 bar; $k_{max} = 10$; Reduced plate heights: $h_{cec} = 1.7$, $h_{p-LC} = 2.5$.
An important feature of merit for a chromatographic technique is peak capacity, which is defined as the number of peaks with unit resolution that can be contained in the column. Peak capacity, then, is a measure of the applicability of a separation technique to highly complex samples (i.e., those containing large numbers of peaks). In comparison to capillary GC, peak capacity in HPLC is limited by the relatively low efficiency of the technique. In contrast, the high separation efficiency of CEC provides increased peak capacity. Table 5 compares typical column efficiency and peak capacity values achievable in CEC and capillary HPLC.

4 INSTRUMENTATION

Although capillary columns offer numerous advantages, their full exploitation is limited by the technological ability to miniaturize the instrumentation properly.

4.1 Columns for Microscale Liquid Phase Separations

4.1.1 Column Performance

All types of packing material offered for conventional HPLC can be used in micro LC. However, submicron size packing materials have been synthesized to increase column performances, considering the fact that pressure drop is no longer a limitation in the micro HPLC format. Moreover, the CEC stationary phase must be able to sustain EOF; thus charged groups need to be incorporated in the packing particles in the case of PCs, or on the capillary surface in OT columns.

Undoubtedly, OT columns offer the highest separation efficiency and highest permeability. Numerous papers have indicated that 1 million plates can routinely be obtained with reduced plate heights on the order of 1.

In micro LC, drawn-packed capillary columns provide efficiencies of 100,000 plates m$^{-1}$ if very long columns are prepared and if long analysis times are acceptable. Such performances are comparable to the packed capillaries, so both types of columns were considered in micro HPLC.

However, in CEC mode the drawn-packed capillaries showed efficiencies of 100,000 plates m$^{-1}$, considerably lower than the 500,000 plates m$^{-1}$ obtained with the packed capillaries. Since the manufacturing of drawn-packed capillaries is much more elaborate and the columns are fragile compared to the fused-silica ones, these columns are no longer used for CEC.

Packed capillary columns of 100–300-µm ID routinely offer 100,000 plates per meter in micro LC with 5-µm particle diameters (C$_{18}$). The reduced plate heights obtained vary between 2.2 and 3, close to the theoretical limit of two accepted for pressure-driven liquid chromatographic systems. Kennedy and Jorgenson demonstrated that columns of ID smaller than 50 µm may yield even smaller reduced plate heights, $h_{\text{min}} = 1.5–1.8$. For these columns the separation impedance ranges from 1300 to 2500; thus longer columns can be used and extremely high separation efficiencies are possible.

Jorgenson explained this effect in a later paper, in which he indicated that microcolumns and conventional columns contain two regions of packing, which are differentiated by their permeability. In the core of the column, the more tightly packed region comprises the first region, while the second region, loosely packed, is near the walls of the capillary.

In CEC two notable benefits are provided by EOF: the flat profile, which as mentioned earlier provides increased efficiency per unit length, and the potential for use of very long columns, which derives from the absence of flow resistance as encountered with conventional pumps. Thus, in CEC reduced plate heights of 1.5 are easily obtainable and total plate counts in excess of 150,000 are possible.

Pressure-driven flow is at present more reproducible than EOF. Column-to-column irreproducibility (RSD (relative standard deviation) larger than 4%) is more significant than run-to-run irreproducibility (RSD currently 1–2%). Some analysts consider that this may be caused by column-to-column irreproducibility in packing, frit fabrication and column surface chemistry.

4.1.2 Column Preparation

Columns in both the OT and packed capillary format are commercially available from companies such as LC packings, Unimicro, Micro-Tech, Keystone and others. However, in most research laboratories the columns are home built using fused-silica tubing available from Polymicro Technologies (Phoenix, AZ, USA) and others using procedures similar to those outlined below.

In OT columns the stationary phases are attached to the walls of the capillary by covalent bonding or by polymer coating. Both procedures require an etching step which activates the silanol groups of the fused silica surface, such that most of them can participate in stationary phase bonding and will not interfere with the retention mechanism. The chemical bond in the first column type, commonly known as a monolayer column, is formed between anchoring groups and molecules that will serve as, and determine, the selectivity of the stationary phase.

Polymer coatings are often preferred to the monomolecular phases because the thick layer of stationary phase ensures an increased sample capacity and solute retention. The in situ procedure comprises the introduction into the column of a mixture containing the functional monomer (often acrylate), initiator, cross-linker and solvent. During the polymerization process,
which can be initiated thermally or via UV radiation, the solvent is evaporated and the oligomers are left immobilized on the surface.\(^{48}\) If suitable anchoring groups are attached to the surface before introducing the polymerization mixture, the polymeric network is covalently bonded onto the surface and the column is more stable. For polyacrylate phases, used in both micro LC\(^{17}\) and CEC,\(^{49}\) the selectivity factors vary from capillary to capillary within 1 and 2\% RSD. Prior to use, the columns are flushed with the appropriate mobile phase.

The quality and lifetime of PCs is directly dependent on the homogeneity of the packed bed. The method most often used for preparing a PC is the slurry packing technique. Dry packing methods, which claim shorter packing times and similar column performances, have also been used for both polar and nonpolar stationary phases.\(^{50}\)

In a typical slurry packing procedure, the packing material and about 1 mL of solvent (selected for compatibility with the packing material; for reversed-phase, acetonitrile and water often yield the best results) are thoroughly mixed and sonicated, then transferred to a stainless steel reservoir. The reservoir contains a metal frit and is connected on one side to a high-pressure pump that is filled with a displacement solvent. The capillary to be packed is connected on one side to a high-pressure pump that is filled with a displacement solvent. The capillary to be packed, the outlet side of which contains a retaining frit (made of silica, Teflon\(^{\text{TM}}\), glass wool or metal) is fitted to the opposite side of the reservoir. In order to ensure the homogeneity of the slurry, a tiny magnetic stir bar placed into the reservoir can be used for mixing. Also the reservoir can be placed in an ultrasonic bath, and sonicated during packing. These features are essential to minimize particle aggregation and settling out of the slurry during packing. Pressure is applied and increased gradually up to about 250 bar. When the column has been packed to the desired length, the system is depressurized and the column can be flushed and conditioned with the mobile phase that is to be used for the analysis.

Alternative packing procedures use different means to force the packing material from the slurry reservoir into the capillary. During electrokinetic packing, a potential ramp (2–30 kV) is applied across the capillary and the slurry reservoir such that the charged particles electromigrate into the column.\(^{51}\) The centripetal-based packing technique uses the centripetal force created by spinning a rotary reservoir onto which numerous capillaries are mounted.\(^{52}\) Both techniques are suitable for mass production of packed capillaries and have been shown to produce columns offering performance characteristics equal to columns made using more conventional means.

4.1.2.1 The “Frit Issue” Before mounting the capillary in the slurry reservoir, the outlet end must be fitted with a porous “plug”, a frit, which will allow the solvent to pass through while the particles stack to form a packed bed. Thus, frits must be able to withstand the high pressures used during the packing procedure. In micro LC, glass wool, metal and silicate frits are used. For CEC, EOF should preferably be supported by the frit, so silicate frits are typically used. They are easier to make\(^{53}\) and can provide porosities very similar to those of packed beds. However, the porosity and surface structure of each of these frits is often sufficiently different from the packed bed to result in peak broadening in micro LC and CEC and gas bubble formation in CEC. Also, instability of the current and baseline signals might occur. Moreover, the columns used for CEC designed for on-column detection must have an additional frit at the column outlet, to keep the bed in place during use. These frits can be obtained by packing porous silica particles and heating the outlet area with a highly focused source of heat such as a Ni–Cr coil or a fiber optic fusion splicer. This will partially adhere the silica spheres together to form a frit; the side effect of applying the heat is the total combustion of the polyimide coating, which renders the column extremely fragile. Various compositions for silicate frit preparations have been tried,\(^{53}\) but none seems to solve the problem completely.

4.1.3 Perspectives

Recent advances in column fabrication include the development of nanosized particles, refinement of chiral selectivity of stationary phases, as well as refinements in the design and fabrication of packing materials specific for CEC separations.

Another trend considers the need to address the frit issue and the best answer seems to be the fritless column. New column designs involve a continuous highly cross-linked porous matrix that can incorporate selective sites, as in the case of “monolithic” columns, or can surround the packing material and hold it in place during the operation of “entrapped” columns.

Numerous papers published recently have studied the synthesis and performance of monolithic columns.\(^{54–56}\) The in situ polymerization of an organic or silicate-based monomer within a capillary column acting as a mold produces a continuous rod of rigid highly porous polymer. For CEC the cross-linked polymer is often provided with charged groups (e.g. sulfonic acid groups) able to sustain the EOF. The main advantages offered by silicate matrices over the synthetic organic polymers include resistance to swelling, stability over time and readily available silanol groups for operating in the CEC mode. On the other hand the synthetic polymers offer a wide variety of functionalities and the possibility to operate at a wider range of pH.

The silicate-entrapped columns are made by trapping the packing particles in a network of silica. Therefore,
aside from the robustness afforded the column, the silicate entrapment provides ionizable silanol groups, which result in an increase in the flow velocity and in radial homogeneity of the electric field. Faster separations and modestly increased efficiencies per unit time can be obtained.

4.2 System Components: Microscale Liquid Chromatography

4.2.1 Pumps

The overall accuracy and precision of any HPLC system is strongly dependent on the ability of the solvent delivery system to deliver stable flow rates. The very small volumes (microliters and nanoliters per minute) required by miniaturized columns place an even more stringent demand on micro LC pumping system. Reciprocating piston pumps, which are the standard in conventional HPLC, lack reproducibility at flow rates below about 0.1 mL min\(^{-1}\). For this reason, these pumps are rarely used in micro LC without a flow splitting device.

The majority of micro LC applications employ syringe pumps. This type of pump, a schematic of which is shown in Figure 5, consists of syringe of fixed volume driven by a stepper motor. Syringe pumps, such as those available from Isco (Lincoln, NE, USA) and Carlo Erba (Italy) are capable of delivering precisely metered flow rates, typically within the range of 0.1–1000 µL min\(^{-1}\). Advantages over reciprocating piston pumps include better reproducibility at low flow rates and pulse-free operation. The main disadvantage of the syringe pump, a limited volume of solvent, is less problematic with the very low flow rates encountered with micro-columns.

4.2.2 Injectors

In general, the sample injection system in micro LC must be capable of introducing very small volumes (e.g., nanoliters) onto the column with a high degree of accuracy and precision. In addition, the injection system must contribute minimally to extra-column peak broadening.

The most common means of sample injection in micro LC are microvalve injectors, such as those produced by Valco (Houston TX, USA) and Rheodyne (Cotati CA, USA). In this type of device, depicted schematically in Figure 6, an internal loop of fixed volume controls the amount of sample injected. Injection volume is varied by changing the sample loop. Injection loops are available commercially from a number of manufacturers in volumes ranging from 60 nL to 1 µL.

The flow geometry and low volume of these injectors permits clean and thorough sweeping of the loop volume, which minimizes peak broadening and tailing.

4.2.3 Detectors

A variety of detection schemes have been employed in micro LC, the most common of which include UV, fluorescence, electrochemical, and mass spectrometric detection. Of these, the optical methods, UV and fluorescence, are the most widely used. With optical detection, the flow cell design is vital in controlling extra-column band broadening; specifically, cell volumes must be extremely small. Ideally, the cell volume should be less than one-tenth of the peak volume; however, decreasing cell volume will generally decrease the detection path length, which reduces sensitivity in accordance with the Beer–Lambert relationship. Thus, optimizing cell design generally involves a compromise between sensitivity and efficiency.

Optical detection in capillary LC can be performed using the capillary column itself as the flow cell. In this mode, known as on-column detection, a small section of the polyimide coating of the capillary is removed downstream from the packed bed, rendering it UV transparent. Incident radiation is directed through a slit, passes through the capillary and strikes a photodetector.
situated opposite the entrance slit (depicted in Figure 7). Advantages of on-column detection include its simplicity and minimal extra-column volume contribution. It is, however, limited by the low sensitivity imposed by the short detection path length.

Alternatively, micro flow cells can be employed with longer path lengths to provide increased sensitivity while contributing only very small volumes to the system. One such cell configuration, available commercially from LC Packings (Amsterdam, the Netherlands), employs a Z-shaped fluid path designed to increase detection path length.

Some limitations of micro flow cells are cost (relative to on-column detection) and problems with coupling to the chromatographic column (e.g. leaks, dead volumes).

Electrochemical detection is particularly attractive for use in micro LC. Used primarily in voltammetric and amperometric modes, electrochemical detection is sensitive, selective, amenable to miniaturization and, in contrast to optical detection, suffers no loss of sensitivity with miniaturized cell volumes. (For a recent review of electrochemical detection in miniaturized separation techniques see Ewing et al.\textsuperscript{58}). DLs in the femtomole range have been obtained with voltammetric detection using a carbon fiber microelectrode coupled to a capillary LC column.\textsuperscript{59}

Alternatively, on-column detection can be performed with fused-silica capillary columns. On-column detection is advantageous primarily owing to its simplicity and minimal extra-column volume contribution. A drawback of this approach, however, is reduced sensitivity due to a substantially reduced detection path length.

4.3 System Components: Capillary Electrochromatography

A block diagram of a typical CEC system is illustrated in Figure 8. The instrument consists of a high voltage (HV) power supply capable of applying a high potential (usually up to 30 kV) and a pair of platinum wire electrodes. The separation capillary is immersed in the inlet and outlet mobile phase reservoirs, forming a complete circuit. In PC CEC, it is usually necessary to pressurize the mobile phase reservoirs in order to minimize the formation of gas bubbles, which can drastically affect EOF.

Sample introduction in CEC is usually achieved via electrokinetic injection. In this technique, the capillary inlet is first removed from the mobile phase vial, immersed into the sample and a voltage applied. The resultant EOF draws a given amount of sample into the capillary. The capillary inlet is then reimmersed in the mobile phase vial and the separation begun. In contrast to capillary LC, in which a known volume of sample is injected by means of a valve, the injection volume in CEC must be determined indirectly from the injection time and the EOF velocity at the voltage used. Because of this, the injection precision is dependent upon the stability of the EOF. Not surprisingly, injection to injection reproducibility tends to be lower in CEC than in capillary LC.

CEC instrumentation is virtually identical to that used in CE, with the exception of external pressurization, a minor modification. This is an added advantage for CEC in that both separation techniques can be performed on the same instrumentation.

Optical detection in CEC is generally in the on-column format. This requires that a detection window be made (as in capillary LC) by removing a small section of the polyimide cladding. As in capillary LC, low detection sensitivity imposed by short cell path lengths is an issue.

Figure 7 Schematic of on-column detection with a packed fused-silica capillary column.

Figure 8 Block diagram of a CEC system.
in CEC. Specially designed detection cells including “Z-cells”, “bubble cells” and the High Sensitivity Detection Cell® marketed by Hewlett-Packard provide increased path lengths, which improve DLs.

Low sensitivity, a major disadvantage of CE, is less a problem in CEC owing to increased sample capacity. The packed bed provides a high surface area of stationary phase on which sample can be accommodated. As a result, CEC allows for larger volume injections without compromising efficiency.

The most common detection scheme in CEC is on-column fluorescence UV. Alternatively, on-column laser induced fluorescence (LIF) is a highly sensitive technique that provides some compensation for the short detection path lengths. DLs as low as 10⁻¹¹ M were obtained for a series of polycyclic aromatic hydrocarbons (PAHs) using CEC/LIF. As discussed in the next section, mass spectrometric detection has been combined with CEC with excellent results.

4.4 Mass Spectrometry Coupling

4.4.1 Micro Liquid Chromatography/Mass Spectrometry

Interfacing a mass spectrometer to a chromatograph can provide a wealth of analytical information. In addition to mass-selective detection, a mass spectrometer can yield structural information that can be used to identify compounds as they elute from the column. In spite of the advantages gained by combining the techniques, interfacing LC to MS has been hampered by practical problems. In contrast to GC/MS, it is only since about 1985 that LC/MS has grown into a widespread technique, with the advent of improved interface and ionization source technology, in particular electrospray ionization (ESI).

The chief problem in coupling LC to a mass spectrometer is the incompatibility that results from the relatively large volumes of effluent from the LC column and the vacuum requirement of the mass spectrometer. Ideally, the LC effluent should be vaporized and the solvent vapor pumped out of the system prior to the gas-phase solutes entering the environment of the mass spectrometer. Eliminating the large volumes of solvent vapor generated by 4.6-mm columns is difficult. Consequently, reducing the volumetric flow through the LC system facilitates coupling of the systems. Thus, with respect to flow rates, micro LC is a more natural match for MS than conventional LC. This, in addition to the inherent advantages of miniaturized columns described earlier, has led to the emergence of micro LC/MS as a powerful analytical tool. (For a thorough review of the theory and practice of capillary LC/MS, see Tomer et al.)

Currently one of the most popular means of interfacing micro LC to MS is via the ESI source. In the typical ESI arrangement, the sample solution passes through a metal capillary tube, to which is applied a potential on the order of 3–5 kV with respect to a grounded counter electrode a short distance from the tip. Electrostatic repulsion results in the ejection of a stream of charged droplets from the capillary tip. Ionized sample molecules, at atmospheric pressure, are desolvated with the aid of a stream of warm nitrogen gas. The gas phase sample ions enter the low-pressure environment of the mass spectrometer through a series of skimmers. Because no sample heating is required, ESI is well suited for application to large, thermally labile molecules (such as many biomolecules). A soft ionization source, ESI yields predominantly molecular ions. For structural elucidation, ESI is often combined with triple quadrupole mass analyzers in which collision-induced dissociation (CID) is employed to induce fragmentation. Typical solution flow rates for ESI are 1–10 μL min⁻¹. Pneumatically assisted ESI or ion spray, in which a nebulizing gas is employed to assist droplet formation, can accommodate higher flow rates, up to 100–300 μL min⁻¹. These flow rates are directly compatible with miniaturized HPLC columns; flow splitting of the column effluent, which reduces sensitivity, is usually not required.

The high mass sensitivity of micro LC facilitates the analysis of volume-limited samples. For this reason, capillary LC/MS is especially useful for biological samples. In particular, capillary LC/ESI/MS has been utilized extensively in protein and peptide analysis. The high resolving power of capillary LC is used to separate complex mixtures of peptide digests, which are subsequently sequenced using tandem MS. One of the most important advantages of the capillary LC format in these sequencing analyses is that only very small amounts of starting material are required. Sequences of peptides have been obtained via capillary LC/ESI/MS with as little as 800 fmol of sample.

Capillary LC/ESI/MS has been employed to study the various peptides that bind to class I major histocompatibility complex molecules. Recognition of these bound peptides by cytotoxic T lymphocytes is an important component of the immune response of the body. Peptide fractions were separated by reversed-phase capillary HPLC and sequence information was obtained by tandem MS using a triple quadrupole instrument. Peptide sequences were obtained with as little as 900 fmol of sample.

Improvements in ESI detection sensitivity gained by reducing column diameter have been demonstrated by Banks. Using a time-of-flight mass spectrometer, measured signal-to-noise (S/N) ratios increased 428-fold upon decreasing column diameter from 2.1 mm to 0.1 mm. A mass DL of 2.5 fmol was obtained for cytochrome-C using the 0.1-mm capillary. Figure 9 is a separation of a mixture containing five proteins (25 fmol each) in less than 7 min using this instrument. These results underscore the power of capillary LC/MS.
LIQUID CHROMATOGRAPHY

Figure 9 Total ion chromatogram of a protein mixture (25 fmol each) obtained with a 100-µm ID HPLC column. (Adapted from Banks, J. Chromatogr., A, 786, 67–73, Copyright (1997) with permission of Elsevier Science.)

4.4.2 Capillary Electrochromatography/Mass Spectrometry

The volumetric flow rates of PC CEC (typically 0.5–2 µL/min) are also ideal for coupling to MS, in particular ESI. For the analysis of neutral solutes, coupling CEC to MS is more straightforward than MEKC because the latter requires relatively high concentrations of surfactants, which in general are incompatible with most MS interfaces.

Since the mid-1990s, several research groups have been active in developing CEC/MS. In 1994, a 50-µm capillary packed with 3-µm particles was coupled to a mass spectrometer using a fast atom bombardment (FAB) interface. The system was used to analyze a series of steroids. In this instrument, the separation capillary was connected to the MS by means of a transfer capillary, which degraded the chromatographic efficiency of the system owing to the extra-column volume contribution of the transfer line. Schmeer et al. coupled 100-µm ID CEC columns directly to an ESI/MS without the need for a transfer capillary. The outlet end of the separation capillary was positioned directly inside the inner steel needle of the ESI source, eliminating the postcolumn peak broadening that occurs with transfer lines. Although supplementary pressure was employed to stabilize the flow rates, bulk flow was generated mainly by EOF. The instrument was used to separate peptide mixtures at picomole levels.

A few of the other applications of CEC/MS to date are the analysis of textile dyes, pharmaceuticals, and DNA adduct mixtures.

CEC/MS is a technique with much promise. The ability to analyze very small sample volumes and the high peak capacity of CEC in combination with the sensitivity and selectivity of MS yields a powerful microanalytical technique.

5 OPTIMIZATION OF ANALYSIS

In order to achieve the “optimum” solution to a particular separation problem, numerous aspects must be considered: analyte structure and matrix complexity, nature of the stationary phase, type of column (capillary or conventional, OT or PC), detection sensitivity and operating conditions (such as mobile phase composition, temperature and pressure).

5.1 Selectivity Optimization

The trends in stationary-phase evolution for micro LC and CEC are similar to those in conventional LC: development of stationary phases able to affect chiral separations or screen components of combinatorial libraries or other complex mixtures.

An interesting approach involves the use of molecular imprinted polymers (MIPs). Specific functional monomers interact through covalent or noncovalent interactions with complementary groups of a template molecule. In a subsequent polymerization step cross-linking polymers react with the monomers and create a macroporous matrix. Extraction of the template leaves cavities complementary to the imprint molecule in both shape and chemical functionality. Prepared in bulk, followed by subsequent grinding and sieving, or prepared in situ, resulting in MIP monolithic columns, or produced as spherical beads, the molecularly imprinted polymers provide extremely selective materials for HPLC and electro-driven separation techniques.

Much effort has been invested in designing MIPs suitable for CEC since the increased efficiency specific to this technique is expected to minimize to an extent the band broadening often encountered in separations using MIPs. Promising results have been obtained in the OT/CEC format where baseline separation of D- and L-dansyl phenylalanine was achieved. Other successful approaches consider the macroporous monoliths, which
demonstrated commercial potential by providing the enantioseparation of phenylalanineanilide and \( \beta \)-adrenergic antagonists propranolol and metoprolol.

5.2 Gradient Separation and Temperature Programming

When separating analytes having substantially different capacity factors, the peaks that elute early tend to be poorly resolved while those that appear later in the chromatogram are broadened, a phenomenon known as the "general elution problem". Solutions to the general elution problem generally employ establishment of a gradient in one (or more) of the following: solvent strength (gradient elution), viscosity (temperature programming) flow velocity (flow programming), and so on. In gradient elution the strength of the mobile phase is continuously increased during a run, while in temperature programming the viscosity of the solvent decreases as the temperature of the capillary situated in an oven is gradually raised. In CEC increasing flow velocity can be accomplished readily by programming a gradual increase in the applied potential.

The generation of reproducible controlled solvent gradients in capillary columns is not an easy task considering the small flow rates (submicroliter per minute) that must be delivered. In CEC the problem becomes even more complex for instrumental design considerations, since in addition to the delivery of a solvent gradient, a high voltage must be applied simultaneously, and from a chromatographic point of view, because variations in solvent composition significantly affect EOF velocity.

One of the first approaches considered the supply of a pressure-driven gradient in parallel with application of high electric field. In order to take advantage of the high efficiency offered by CEC, the separation must be performed using solely EOF. Therefore, the most embraced approaches consider designs that use HPLC pumps to deliver mobile-phase gradients to the inlet of the separation column. Mixtures of drugs, PTH (parathyroid hormone)-aminoacids (from the Edman degradation of a peptide) and steroid hormones were resolved using a mobile-phase splitting device.

Another type of gradient elution system proposed for CEC provides a pure electroosmotically driven flow. It is composed of two fused silica capillaries each connected to a programmable high-voltage power supply and to a different mobile phase reservoir. The applied voltages are varied during the run such that as the flow of one mobile phase increases (as the corresponding potential increases) the amount of the other mobile phase decreases (the applied potential decreases) in a manner that ensures a constant resultant flow. The outlets of the solvent delivering capillaries are attached through a T connector to the inlet of the separation column. System feasibility was proven when 16 PAHs were separated in less than 90 min.

As opposed to conventional LC columns, capillary columns have a small heat capacity, which confers another advantage: the use of temperature programming. The simplicity of the instrument requirements (an oven with temperature control) allows the consideration of temperature programming as a replacement for or augmentation of gradient elution for thermally stable analytes. A comparative study was performed on reversed-phase packed capillaries for separations of alkylbenzenes at temperatures varying from 30 to 80°C and mobile phases of 60–80% acetonitrile in water. The results indicate that a 5°C change in column temperature is equivalent to 1% change in acetonitrile concentration. Thus, temperature programming can be used alone or in conjunction with gradient elution to tune the separation of closely eluting compounds finely.

The issue of temperature programming is a bit more complicated in CEC since, besides retention factors, changes in temperature have a considerable effect on the viscosity of the mobile phase, thus on the EOF. Moreover, when working with relatively volatile solvents it is desirable to operate at decreased temperature in order to avoid bubble formation, which has a dramatic effect on the EOF. However, it has been shown that by raising the temperature 25–50°C the enhancement of mass transport provides a three-fold increase in separation speed.

5.3 Ultra High-pressure Micro Liquid Chromatography

Since the mid 1980s numerous aspects of micro LC and CEC instrumentation have been studied, and pressure or voltage limits once considered fixed have been pushed further in an attempt to increase the performance of miniaturized systems.

Jorgenson, MacNair and Lewis have indicated a possible new direction in micro LC development, the use of extremely high pressure. It has long been recognized that small particles can significantly decrease plate height, though they simultaneously generate large back pressures which impede the use of long columns and increase analysis time by dictating lower flow rates. By using pressures as high as 1400 bar (20 000 psi), Jorgenson et al. obtained reduced plate heights of 1.4 for 66-cm long packed capillaries, accompanied by a significant reduction in the analysis time.

6 APPLICATIONS

6.1 Micro Liquid Chromatography

Micro LC has been employed in a variety of different applications. A number of textbooks and literature
reviews\(^4,^8\) present thorough discussions of the various analytical problems to which micro LC has been applied. In this space, only a small sample of these is presented; the interested reader is referred to the cited literature for a more detailed listing.

An interesting application of micro LC that exploits the technique’s small volume requirement, is the analysis of single biological cells. In 1992, Jorgenson et al. published a method in which the catecholamines norepinephrine and epinephrine were determined in a single bovine adrenomedullary cell.\(^8,^9\) These authors employed 42 and 50-µm ID fused-silica capillary columns packed with 5-µm C\(_{18}\)-coated silica particles. Amperometric detection, which was employed using a carbon fiber microelectrode, yielded DLs in the attomole range. A chromatogram obtained from a single adrenomedullary cell is shown in Figure 10. This research group also published a method for the analysis of single neurons using OT LC in 1989.\(^5\)

Separations of enantiomers are becoming increasingly important and present tough challenges to analysts. One approach to chiral separations in LC is to use a conventional stationary phase and add a chiral selector (e.g. cyclodextrins) to the mobile phase. One of the disadvantages of this approach is that these additives are often quite costly. However, the very low column volumes and solvent consumption rates of miniaturized columns facilitate the use of expensive additives because only a very small amount is required. In a paper by Takeuchi et al.,\(^8\) capillary LC with a cyclodextrin additive was employed to obtain separations of 1-ferrocenylethanol and dansyl-phenylalanine enantiomers. In this method, 350-µm ID capillaries were packed with 5-µm ODS (octadecylsilane)-5 particles. Various amounts of methylated β-cyclodextrin were added to the aqueous acetonitrile mobile phase. A separation of ferrocenylethanol enantiomers is shown in Figure 11.

A short listing of micro LC applications is presented in Table 6.

### 6.2 Capillary Electrochromatography

CEC is a relatively new technique that is receiving a great deal of attention from analytical chemists. For this reason, the number of publications on CEC is growing rapidly, as are its applications. A review by Bartle et al. includes a comprehensive listing of CEC applications up to the end of 1996.\(^9\) In addition to those discussed below, a few applications of CEC are presented in Table 7.

Published in 1995, the separation of 16 PAHs shown in Figure 12 demonstrates the separation power of CEC.\(^6\) PAHs are environmental contaminants classified by the US Environmental Protection Agency as “priority” pollutants. This separation was performed with a 75-µm capillary packed with mixture

(90:10) of 3-µm ODS and 1-µm nonporous silica. On-column LIF detection yielded mass DLs on the order of 10^-19 mol. Efficiencies of 100 000–150 000 plates m^-1 were obtained.

In 1997 Euerby et al. published a paper on the applications of CEC in pharmaceutical analysis. Here, this group reported separations of a variety of compound classes including peptides, nucleotides, steroids, diuretics and acidic drugs. Figure 13 illustrates a separation of four commonly used diuretics performed on a commercially available 3-µm CEC Hypersil® C-18 capillary. Efficiencies ranging from 149 000 to 344 000 plates m^-1 were obtained.

An interesting application of CEC was recently reported in which inorganic ions were separated by ion exchange capillary electrophromatography (IEEC). Anions such as I^-, IO_3^- and TeO_4^- are often present in nuclear waste materials in locations such as the US Department of Energy site at Hanford, Washington (USA). For this reason, the analysis of such ions constitutes an important environmental application. In this IEC method, silica-based particles modified with an anion exchanger, 5-µm Nucleosil® SB, were packed into 75-µm fused-silica capillaries. UV detection was employed to analyze iodide, iodate and perrhenate (ReO_4^- was used as a surrogate for TeO_4^-). Direct comparisons of the IEC method with capillary zone electrophoresis (CZE) revealed a 20-fold lower DL for the former owing to enhanced sample capacity. These nuclear waste sites are an increasingly important environmental concern, as leaks from underground storage containers are damaging to the environment. Thus, the need exists for improved analytical techniques with which to monitor these sites. IEC may provide an alternative to CZE for analyzing low levels of inorganic ions leaching from such sites.

7 FUTURE PERSPECTIVES

In spite of the many advantages afforded by miniaturized chromatographic techniques, it is quite doubtful that micro LC and/or CEC will ever completely supplant conventional scale HPLC as the workhorse in the typical analytical laboratory. A more realistic view is that these techniques are complementary in nature. To be sure, capillary LC will continue to play a central role in biological analyses, especially in protein sequencing. In general, the technique is likely to be employed in cases where sample is volume limited. CEC is currently undergoing a period of intense growth; the number of publications has increased dramatically since 1995. The high separation efficiencies obtained in practice, in agreement with theory, are encouraging. Also promising is the fact that many of the CEC separations reported thus far have employed typical HPLC packings, which will simplify method transfer between the techniques. The future of CEC is most likely in applications where high peak capacity is required (e.g. very complex samples), and/or in rapid highly parallel, automated, perhaps chip-based analysis.

REFERENCES

Normal-phase liquid chromatography (NPLC) is a technique that uses columns packed with polar stationary phases combined with nonpolar or moderately-polar mobile phases to separate the components of mixtures. The rate at which individual solutes migrate through NPLC columns is primarily a function of their polarity. Less polar solutes move the fastest and therefore exit the column and are detected first, followed by solutes of increasing polarity which move more slowly. However, polarity can sometimes play a secondary role relative to a solute's ability to experience a specific interaction with active sites on the stationary phase surface. The importance of these specific solute–stationary phase interactions in NPLC gives it some unique advantages over the more widely practised reversed-phase liquid chromatography (RPLC) technique. RPLC utilizes nonpolar stationary phases and aqueous-based polar mobile phases, and the elution order of solutes in a mixture is related to their hydrophobicity, not polarity; more polar solutes move the fastest and appear first, followed by solutes of decreasing polarity. RPLC is useful for separating mixtures in which components differ in molecular weight and/or water solubility. However, NPLC is preferred for many separation problems, including those in which the water solubility of sample compounds is limited. In addition, NPLC is a better technique for separating compounds that differ in the number or character of functional groups and is particularly useful for separating many types of isomers.

1 INTRODUCTION

1.1 Normal-phase Liquid Chromatography

The extent to which solutes are slowed by interactions with the stationary phase as they move through a liquid chromatography (LC) column is broadly referred to as retention. In NPLC retention is the result of a complicated set of specific molecular interactions, including interactions between the solute and stationary phase, mobile phase and stationary phase, and solute and mobile phase. In NPLC the stationary phase is usually more polar than the flowing mobile phase and the order of retention generally tracks the polarity of components in a mixture: less polar first, followed by solutes of increasing polarity.

The absolute magnitude of retention in a particular NPLC column, as in most LC techniques, is normally controlled by the "solvent strength" of the mobile phase. Note that in LC, the mobile phase is often referred to as the solvent. An increase in the solvent strength of the mobile phase results in faster migration of solutes and a general decrease in solute retention times.

In NPLC, solute and mobile phase molecules compete for polar active sites on the stationary phase surface. Changes in mobile phase polarity are thus
used to adjust solvent strength and optimize retention times. With modern liquid chromatographs solvent strength is normally controlled by combining a nonpolar weak solvent such as hexane with moderately polar strong solvents such as isopropanol. In binary (or in ternary/quaternary) mobile phases, the weaker solvent is usually designated the “A” solvent, while the additional solvent(s) are known as modifiers and designated the B, C, etc. solvents. Generally, increasing the modifier content in the mobile phase increases solvent strength and thus decreases retention.

The relative positions of and spacing between solutes in a normal-phase liquid chromatogram can be optimized through changes in both solvent strength and “solvent selectivity”. Solvent selectivity refers to the totality of molecular interactions a solvent is capable of, including dispersion, dipole–dipole, and acid–base and hydrogen-bonding interactions. In NPLC, varying the magnitude (solvent strength) or nature (solvent selectivity) of the solvent–stationary phase interactions by changing the mobile phase modifier will affect solute retention. For example, resolution enhancement can often be accomplished by changing from a hexane/isopropanol mobile phase to hexane/dichloroethane, or by changing the amount of a very strong polar modifier such as methyl- tert-butyl ether (MTBE) in a hexane/MTBE binary mixture.

1.2 Normal-phase Liquid Chromatography Compared with Reversed-phase Liquid Chromatography

By the mid-1970s, the ability to attach virtually any functional group, polar or nonpolar, to silica particles and make bonded stationary phases led very quickly to the rapid development of RPLC. In contrast to NPLC, RPLC utilizes nonpolar bonded stationary phases (e.g. octadecylsilane (ODS), often abbreviated C18) and aqueous-based polar mobile phases. Retention is based largely on a solute’s hydrophobicity, and elution order is thus generally the reverse of that in NPLC: more polar solutes first, followed by solutes of decreasing polarity. RPLC proved to be applicable to a wide variety of separation problems and now represents about 80% of all high-performance liquid chromatography (HPLC) applications. It is useful for separating mixtures in which components differ in molecular weight and/or water solubility.

However, NPLC is still a useful approach for many separation problems, including those in which the water solubility of sample compounds is limited. In addition, NPLC is the preferred mode for separating compounds that differ in the number or character of functional groups, and is particularly useful for separating many types of isomers. Polar bonded phases useful for NPLC are now available, providing a wider array of stationary phase choices than traditional liquid–solid chromatography (LSC) adsorbents such as silica and alumina. Because of the specificity of retention in NPLC, the use of such polar bonded phases in the normal phase mode actually provides a wider variety of optimization choices than are possible with reversed-phase columns.

2 FUNDAMENTALS OF RETENTION

2.1 Liquid–Solid Chromatography: the Adsorption–Displacement Model

The most successful models of retention in LSC are those of Snyder et al.\textsuperscript{1–4} and Soczewinski.\textsuperscript{5} Both models describe retention as resulting from competitive adsorption between solute and solvent (mobile phase) molecules for active sites on the stationary phase surface. Each assumes a surface monolayer of solvent and/or solute molecules, but Snyder’s model further assumes a homogeneous surface so that adsorption energies of both solute and solvent molecules are constant.

The stoichiometry of solute–solvent competition in Snyder’s model can be expressed by Equation (1):

\[ X_m + nS_a \leftrightarrow X_a + nS_m \]  \hspace{1cm} (1)

where \( m \) and \( a \) refer to solute (\( X \)) and solvent (\( S \)) in the mobile and adsorbed phases, respectively. The coefficient \( n \) represents the ratio of areas occupied by solute and solvent molecules, respectively, on the adsorbent surface and reflects the fact that a solute molecule must displace all solvent molecules that restrict its access to an adsorption site. The Soczewinski model is similar to Snyder’s, but it does not assume a homogeneous surface. Rather, the surface is considered to be energetically heterogeneous, with adsorption occurring entirely at high-energy sites, leading to discrete, one-to-one complexes of the form (Equation 2):

\[ X_m + nS^* \leftrightarrow nS_m + X^* \]  \hspace{1cm} (2)

where \( A^* \) is an active surface site and \( n' \) refers to the number of substituents on a solute molecule that are capable of simultaneously interacting with the active sites. Equation (2) thus takes into account the possibility of multisite attachment. By assuming a binary mobile phase consisting of a weak, nonpolar solvent (e.g. hexane) and a strong, polar solvent modifier (e.g. isopropanol), the adsorption of the weak solvent can be ignored and retention predicted by Equation (3):

\[ \log k = \text{constant} - n \log N_b \]  \hspace{1cm} (3)
Snyder has pointed out a more convenient form of Equation (3) that is equally reliable (Equation 4):

$$\log k = \text{constant} - n \log(\%B)$$

(4)

In Equations (3) and (4), $k$ is the capacity factor and $N_0$ the mole fraction of the strong solvent in the mobile phase. The capacity factor is a relative parameter which normalizes solute retention volume ($V_t$) or retention time ($t_r$) in terms of column void volume ($V_m$) or void time ($t_0$) (Equation 5):

$$k = \frac{V_t - V_m}{V_m} = \frac{t_r - t_0}{t_0}$$

(5)

Equations (3) and (4) predict that a plot of $\log k$ against $\log N_0$ or $\log(\%B)$ should yield a straight line. In the Snyder model, the slope of this line should be the ratio of the molecular areas of solute and solvent, whereas Sozcewinski’s model predicts that the slope is the number of strongly adsorbing substituent groups on the solute.

### 2.2 Localization and Secondary Solvent Effects

Neither the Snyder nor Sozcewinski model is entirely satisfactory as presented for describing retention in NPLC, particularly when bonded stationary phases are used. Such normal bonded phase (NBP) LC columns do contain strongly adsorbing active sites (Soczewinski model), but solute molecular area, not just polar substituents, is known to play an important role in competitive adsorption (Snyder model). In addition, neither model accounts for so-called secondary solvent effects. These effects, which arise from solute–solvent interactions in both the mobile and adsorbed phases, lead to some very useful changes in retention. A rigorous description of retention in NPLC, and thus separation optimization, must therefore include some discussion of the highly specific solute–stationary phase, solvent–stationary phase, and solute–solvent interactions encountered with the types of polar surfaces and molecules commonly used in NPLC. Detailed reviews of these effects can be found in Snyder and Dorsey and Cooper.

Localization refers to the phenomenon which occurs when the strength of strong polar interactions (e.g. dipole–dipole, hydrogen bonding) between solute or solvent molecules and active sites on the stationary phase surface exceed the thermal energy of solute or solvent. When this happens, the solute/solvent molecules are preferentially located in the vicinity of the active site, rather than delocalized in a surface monolayer. The competition between solutes and solvent molecules for localized positions on the stationary phase leads to delocalization of previously localized molecules.

Localization phenomena give rise to some of the most interesting and useful retention behavior in NPLC. For example, it has been established that, at least for solid adsorbents such as silica and alumina, solvent localization is more important in determining mobile phase selectivity than a solvent’s acidity, basicity or dipolarity. Snyder has presented a solvent optimization strategy that is largely based on these localization effects. It should be noted that this delocalization competition occurs between solutes and the polar modifier, since the weaker solvent (normally hexane) does not localize.

There are actually a number of different types of localization commonly encountered in NPLC, and these are depicted in Figure 1. Site-competition delocalization occurs when localizing polar solutes and modifier molecules have unrestricted access to the active surface site. In this case, an increase in modifier content in the mobile phase will weaken solute localization and retention will decrease to a greater extent than predicted from a solvent strength value determined with nonlocalizing solutes. For example, MTBE, like most basic, localizing solvents, produces a stronger mobile phase than predicted when used with silica and certain bonded phase columns. Correcting for such an effect is straightforward because the solvent strength of the modifier can be adjusted. However, this must be done on a specific solvent–stationary phase basis. The necessary solvent strengths and/or corrections for the most widely used normal-phase columns and polar modifiers have been tabulated.

Restricted-access delocalization (Figure 1b), which occurs when polar modifier and solute molecules compete for localization on rigid, fixed surface-active sites where
access is highly limited, is more difficult to predict and quantify. When the modifier content is low it will localize and disrupt solute localization and the effective solvent strength of the modifier will be relatively large. However, with increasing coverage of the adsorbent surface, a point is reached at which adsorbed modifier molecules interfere with further modifier localization. The effective solvent strength of the modifier thus decreases with increasing surface coverage. Since this decrease in modifier solvent strength is non-linear, a simple modification to modifier solvent strength is not suitable. Rather, a delocalization function is required which can be used to adjust the modifier solvent strength.\(^{(10–12)}\)

A localization effect that is unique to bonded-phase adsorbents is mixed-site delocalization. This occurs because unreacted, “residual” silanol groups (Si–OH) on the underlying silica support can influence the character of the bonded phase through hydrogen bonding with its polar functional group. This hydrogen bonding can be disrupted by the presence of strongly localizing modifiers (Figure 1c). This mixed-site delocalization effect is most pronounced in weaker, less polar bonded phase columns such as cyano-silica.\(^{(13)}\)

Secondary solvent effects arise from specific, polar interactions between solute and solvent molecules. While they are normally considered “secondary” in their importance on retention relative to solute–solvent–stationary phase interactions, they often provide an effective means of altering retention selectivity. There are three different types of solvent effects observed in NPLC. The first and most straightforward occurs in the mobile phase when there is a specific polar interaction between solutes and the mobile phase modifier. This type of solvent effect, which is not balanced by a corresponding effect in the stationary phase, decreases retention of the interacting solute and is thus considered a negative effect.

A second type of solvent effect is observed when there is a strong affinity between the stationary phase and polar modifiers, resulting in an excess concentration of modifier in the surface adsorbed layer. If a solute experiences a strong interaction with this modifier, and the concentration of modifier is higher in the stationary phase than in the mobile phase, the solute–solvent interaction will increase retention. This second type is thus considered a positive effect because it increases retention.

The third type of solvent effect is also due to excess modifier in the stationary phase, but in this case the modifier is so strongly adsorbed it is sterically hindered from interacting with an adsorbed solute which is nonetheless experiencing a strong interaction with the modifier in the mobile phase. This unbalanced interaction decreases retention and is thus a negative effect.

3 STATIONARY PHASES

3.1 Solid Adsorbents

Silica gel is by far the most popular stationary phase for LSC. Its rigidity provides structural stability at the high pressures used in HPLC and it can be synthesized with a wide variety of particle sizes, surface areas, and pore diameters. For analytical separations, 5–10 µm porous silica is most commonly used, but larger silica with less porosity can be obtained.

In addition to its advantageous physical attributes, silica provides a very polar surface with a high concentration of active sites. The active sites on silica are Si–OH groups (silanols), and most chromatographic-grade silicas have Si–OH concentrations of ~8 µmol m\(^{-2}\). Unfortunately, not all silanols are identical, which leads to a significantly heterogeneous surface and, in many cases, “peak tailing” of highly polar solutes. For this reason, small amounts of water are often added to NPLC mobile phases to deactivate the higher-energy silanols.

Silanols are weakly acidic (pK\(_a\) 5–7), and thus care in the choice of the type of silica is necessary if basic solutes are to be separated. So-called Type A silicas contain a high concentration of highly-acidic “free” silanols and are thus not appropriate stationary phases for strongly basic solutes unless special conditions are employed. Type B silicas are dominated by less acidic geminal and associated silanols. Columns made from these Type B silicas have been shown to be useful for normal phase separations of highly polar and basic solutes.\(^{(14)}\)

For samples that are strongly basic or acid-sensitive, alumina is the adsorbent of choice. Alumina is weakly basic, and strongly acidic and base-sensitive compounds cannot normally be chromatographed on it. Retention of neutral solutes is similar on alumina and silica, but alumina lacks many of the physical attributes of silica that have led to silica’s prominence. Thus, unless precluded by its acidic character, silica is normally the LSC stationary phase of choice.

Other adsorbents which have been suggested as possible alternatives to silica and alumina include zirconia and titania. Both of these solids appear to be more basic than silica, much like alumina.\(^{(15)}\) While each has some unique chromatographic properties, neither adsorbent is widely used today.

3.2 Bonded Phases

Chemically-bonded stationary phases have two distinct advantages over solid adsorbents for NPLC. First, derivitization of silica gel with a polar organic functional group provides a much more homogeneous surface than bare silica. Even though steric hindrance by adjacent ligands normally prevents complete reaction
of all surface silanols, a bonded phase packing is much more homogeneous than bare silica and deactivation procedures such as addition of water to the mobile phase are no longer necessary.

A second, more subtle, but ultimately more significant advantage of NPLC bonded stationary phases is that they allow chromatographic selectivity to be enhanced through adjustment of both the stationary and mobile phases. Because retention in NPLC is governed primarily by competitive solute–stationary phase and solvent–stationary phase interactions, changing the column as well as the mobile phase can optimize absolute and relative retention of solutes in a mixture. This is in contrast to RPLC, where the stationary phase, while not a completely passive participant in retention, is nevertheless much less important than the mobile phase.

Virtually all NPLC bonded phases are prepared by reacting a monochloroalkylsilane with silanols on the surface of silica gel. This reaction results in an alkylsilane attached to the silica surface via a silyl ether bond (Si–O–Si). The desired functional group used to produce the specific character of the bonded phase is located at the end of the alkyl chain opposite from the ether bond. The alkyl chain is referred to as the “spacer”; in NPLC these spacers are normally only 2–3 carbon atoms in length.

The most widely-used NPLC bonded phases are cyanopropyl-silica (cyano), aminopropyl-silica (amino), and 1,2-dihydroxypropyl-silica (diol). In addition, a number of other functional groups have been used to produce highly selective NBP columns (e.g. phenylpropyl columns are useful for some highly specific applications). However, the cyano-, amino-, and diol-silica columns are now the most popular. This is due in great part to their widely different retention characteristics and moderate polarity.

The diol column is acidic, the amino column moderately basic, and the cyano column a moderate dipole–dipole interactor. These three columns together provide virtually all the retention characteristics necessary for efficient optimization of sample resolution. It has even been suggested that these three phases form a “stationary phase selectivity triangle” similar to the solvent selectivity triangle used to pick mobile phase solvents (Figure 2).\textsuperscript{(4,16)} In chromatography, a selectivity triangle is used as a guide for producing the most dramatic changes in chemical characteristics of mobile and/or stationary phases during optimization experiments. Cyano, diol and amino columns appear to provide these dramatic differences in retention characteristics.

4 MOBILE PHASES

4.1 Common Solvents Used in Normal-phase Liquid Chromatography

A wide variety of organic solvents have been used as mobile phases in NPLC, ranging in polarity from fluorocarbons to methanol. Liquids with low boiling points and low viscosities are preferred. In addition, it should be noted that in normal-phase chromatography the mobile phase should be less polar than all sample components. In recent years there has been a tendency to choose from a rather limited number of available solvents, making solvent optimization more efficient. Hexane (or pentane) has become the nonpolar solvent of choice, although isooctane is sometimes used. For very nonpolar samples, fluorocarbons may be required.

Most NPLC separations require a mobile phase more polar than hexane. While this can be accomplished with a single solvent, it is actually more convenient to combine hexane with a much stronger solvent and adjust the relative proportions of the two solvents to obtain the correct solvent strength. In such binary mixtures, hexane is the weak solvent (normally designated the A solvent) and the polar solvent the strong solvent (the B solvent). The strong solvent is also frequently referred to as the “modifier”. Solvents commonly used as modifiers include chloroform, methylene chloride, dichloroethane, ethyl acetate, MTBE, tetrahydrofuran (THF), and alcohols such as methanol or isopropanol. When very strong (i.e. very polar) mobile phases are required, hexane can be omitted and one of the polar modifiers used alone or in combination with another modifier.

4.2 Solvent Strength

Retention in NPLC is determined by competitive adsorption between solute and solvent molecules at the stationary phase surface. Thus, the greater the affinity of
the solvent for the stationary phase, the greater is its solvent strength. However, because of the polar interactions involved in NPLC and the specific localization effects that result, a solvent’s apparent strength can vary from column to column. There is thus no absolute scale of solvent strength in the normal-phase mode that is useful for all the different columns available. However, a number of empirical scales are available for predicting and/or controlling retention. In LSC the adsorption solvent strength parameter \( e^0 \) is most useful. This parameter is defined as the adsorption energy per unit cross-sectional area of solvent. Table 1 contains \( e^0 \) values for commonly used normal-phase solvents.\(^8\) For normal bonded-phase LC, empirically-determined solvent strengths have been published for dichloromethane, chloroform and MTBE when used with cyano, amino and diol columns.\(^9\) These solvent strengths are summarized in Table 2.

As noted, it is much more convenient to mix solvents of different polarity in the correct proportions than to find a single solvent of just the right solvent strength and selectivity. This involves combining a nonpolar solvent with a polar solvent which alone would be too strong. These two solvents are then blended empirically to give the correct solvent strength and optimum range of modifier content in the mobile phase, but is described by Equation (6).

\[
E_{ab} = E_a + \frac{\log[N_b 10^{n_b(E_a-E_b)} + 1 - N_b]}{an_b}
\]  

(6)

Here, \( E_{ab} \) is the solvent strength of the mixture, \( E_a \) and \( E_b \) the pure solvent strengths of solvents a and b, respectively, \( N_b \) the mole fraction and \( n_b \) the molecular area of the modifier, and \( a \) an adsorbent activity factor normally taken as unity in modern analytical columns. However, Equation (6) can be greatly simplified if hexane is the weak solvent (A) and the fraction of modifier (B) is not too low (Equation 7).

\[
E_{ab} = E_b + \frac{\log N_b}{an_b}
\]  

(7)

Careful examination of Equation (6) or (7) reveals that binary solvent strengths increase rapidly with increasing modifier content at low modifier levels and less dramatically at higher modifier levels.

It is sometimes necessary to change the polar B solvent to optimize solvent selectivity (see next section). When carrying out such selectivity optimization experiments it is convenient to maintain a constant solvent strength \( E_{ab} \). This can be accomplished by using Equation (6) or (7) and the appropriate solvent strengths and physical parameters. Alternatively, published solvent-strength nomographs provide the same information for silica and cyano or amino bonded-phase columns.\(^8\)

### 4.3 Solvent Selectivity

Once the correct solvent strength has been established (i.e. a solvent strength that produces sample capacity factors in the range of 0.5–20\(^8\)), it is frequently necessary to further enhance sample resolution through optimization of solvent selectivity. Solvent selectivity refers to the totality of molecular interactions a solvent is capable of, including dispersion, dipole–dipole, and acid–base and hydrogen-bonding interactions. In NPLC, these molecular interactions are exploited in both the stationary and mobile phases. In the stationary phase solvent localization plays a critical role in determining retention selectivity, particularly when silica columns are used. Specific molecular interactions in the mobile phase generally play a lesser role in controlling selectivity and are thus referred to as secondary solvent effects. However, in the weaker, less polar bonded phase columns (cyano, amino, diol), these secondary solvent effects

| Table 1 | Solvent strength values of some common normal-phase solvents when used with solid adsorbents\(^a\) |
| --- | --- | --- | --- |
| Solvent | Silica | Alumina |
| Heptane | 0.01 | 0.01 |
| Hexane | 0.01 | 0.01 |
| Isooctane | 0.01 | 0.01 |
| 1-Chlorobutane | 0.20 | 0.26 |
| Chloroform | 0.26 | 0.40 |
| Dichloromethane | 0.32 | 0.42 |
| Ethyl acetate | 0.38 | 0.58 |
| THF | 0.44 | 0.57 |
| Acetonitrile | 0.50 | 0.65 |
| Methanol | ∼0.7 | 0.95 |

| Table 2 | Solvent strength values of some common normal-phase solvents when used with bonded-phase columns\(^a\) |
| --- | --- | --- | --- |
| Solvent | Pure solvent strength |
| | Cyano | Amino | Diol |
| Chloroform | 0.106 | 0.143 | 0.097 |
| Dichloromethane | 0.120 | 0.141 | 0.096 |
| MTBE | 0.049 | 0.124 | 0.071 |

The fundamental rule of mobile phase selectivity optimization in LC is that the greatest change in selectivity occurs when molecular interactions between solute, solvent and stationary phase are dramatically changed. These dramatic changes in solvent selectivity can be visualized using the selectivity triangle\(^1\) which positions solvents in a triangle based on the relative importance of their proton acceptor, proton donor, and dipole–dipole characteristics. The most dramatic changes in solvent characteristics occur when a solvent from one apex of the triangle (e.g. proton donors) is replaced by one from another apex (e.g. proton acceptors). This has led to the use of three modifiers for solvent selectivity optimization in LC. Since these three modifiers represent regions of the selectivity triangle, they are sometimes referred to as the “inner triangle”. In NPLC, the inner triangle would normally be formed with chloroform (proton donor), MTBE or THF (proton acceptor), and dichloromethane or dichloroethane (dipole). The solvent selectivity triangle with the normal-phase inner triangle superimposed is depicted in Figure 3. This “inner triangle” has been shown to produce large selectivity changes in cyano, amino and diol bonded-phase columns.\(^9,16\)

SOLVENT SELECTIVITY IN SILICA COLUMNS, HOWEVER, IS DOMINATED BY THE ABILITY OF A SOLVENT TO LOCALIZE. FURTHERMORE, BECAUSE OF THE ACIDIC NATURE OF THE ACTIVE SITES ON SILICA (SILANOLS), BASIC LOCALIZING SOLVENTS SHOW DIFFERENT SELECTIVITIES THAN NONBASIC LOCALIZING SOLVENTS. THESE OBSERVATIONS LED TO AN ALTERNATIVE SELECTIVITY TRIANGLE WHICH EMPHASIZES LOCALIZATION EFFECTS AND INCLUDES A BASIC LOCALIZING SOLVENT (MTBE), A NONBASIC LOCALIZING SOLVENT (ACETONITRILE OR ETHYL ACETATE), AND A NONLOCALIZING SOLVENT (METHYLENE CHLORIDE OR ETHYLENE DICHLORIDE).\(^20\) THIS LOCALIZATION-BASED INNER SELECTIVITY TRIANGLE IS ALSO INCLUDED IN FIGURE 3.

Chromatogr.*, 499, 177–196 (1990).)
4.4 Aqueous Mobile Phases

While most NPLC mobile phases are made of either polar organic solvents or mixtures of a polar and nonpolar solvent, there are some applications where water is an effective additive. It was noted earlier that silica columns are the strongest NPLC stationary phases and are characterized by a wide variety of silanol adsorption sites. Because water binds very strongly to these silanols, small variations in the water content of the mobile phase can lead to dramatic changes in solute retention. These variations in retention can be largely prevented by purposefully adding small amounts of water to the mobile phase.

Aqueous-based mobile phases are also appropriate for very hydrophilic samples that do not easily dissolve in organic solvents. Frequently, special columns are used with aqueous mobile phases resulting in a unique type of normal-phase separation referred to as HILIC. Mobile phase strength is varied by adding a water-soluble organic solvent. Unlike “normal” NPLC, however, increasing the polar organic modifier content leads to an overall increase in solute retention. This behavior is demonstrated in Figure 4, which contains chromatograms of a cyclopeptide mixture separated on an HILIC column with various water/acetonitrile mobile phases.\(^{(21)}\)

5 OPTIMIZATION STRATEGIES

5.1 Mobile Phase Optimization

Mobile phase optimization begins by establishing the correct solvent strength: that is, a solvent strength that yields solute capacity factors in the range of 0.5–20. As noted previously, solvent strength is normally set by mixing a weak solvent with a strong polar modifier. Hexane is the weak solvent of choice unless a very strong mobile phase is required. In such cases a more polar weak solvent such as methylene chloride or MTBE is more appropriate. Solvent strength is optimized through a series of experiments in which the composition of the polar modifier is increased, or alternatively with a gradient elution experiment. Because of the importance of localization effects in NPLC, solvent strength optimization can frequently provide the necessary retention selectivity.

If an appropriate solvent strength and selectivity cannot be found with a single modifier, a change in modifier type is required. This involves choosing a second polar modifier from a different region of the selectivity triangle (Figure 3). This modifier is added to the weak solvent at a level which produces the same optimized solvent strength as the original mixture. The correct level of new modifier can be estimated via Equation (6) or (7), or by using published nomographs.\(^{(8,17)}\) In this way the original overall range of sample capacity factors which was optimized in the solvent strength experiments should remain roughly constant but the relative positions of sample components might be altered through localization and secondary solvent effects. If this second solvent mixture still does not provide adequate resolution of all sample components, a third can be tried, again keeping solvent strength constant. Here, the solvent modifier should come from a corner of the selectivity triangle not represented in the first two solvent mixtures.

With silica columns the inner solvent selectivity triangle that emphasizes localization effects produces the most dramatic changes in retention selectivity.\(^{(8,19)}\) The dominance of these localization effects in determining the selectivity of polar bonded-phase columns has not yet been established, however. Significant differences in the selectivities of bonded-phase columns have been accomplished with the traditional inner triangle that emphasizes proton donor, proton acceptor and dipole characteristics.\(^{(9,16)}\) Thus, the appropriate strong solvents to use when changing modifier type for selectivity enhancement appear to depend on the column type.

As an example of such a mobile phase optimization, imagine that an amino column is chosen to separate the components in a particular sample. Initial solvent strength experiments with hexane and chloroform then determine that a 90:10 (v/v) mixture of hexane–chloroform gives the correct capacity factor range. From the data in Dorsey and Cooper\(^{(7)}\) the solvent strength of this composition is estimated to be 0.044. A change in selectivity is then accomplished by changing to a hexane/MTBE mixture, and the data\(^{(7)}\) indicate that a 80:20 hexane–MTBE composition also has a solvent strength of 0.044. Finally, the third solvent mixture would be hexane–dichloromethane at a 90:10 ratio, since the solvent strengths of chloroform and dichloromethane are approximately equal when used with an amino column.

A more elaborate mobile phase optimization scheme has been proposed and shown to be effective in developing NPLC separations of very complex mixtures.\(^{(22)}\) This approach again begins by establishing the correct solvent strength using a binary mobile phase, either through incremental, decreasing changes in the amount of strong solvent, or through a “reversed-gradient” experiment. Then, a series of seven isocratic experiments are carried out in which the three modifiers from an inner triangle are mixed in a systematic way, all the while maintaining an approximately constant solvent strength. In the example cited the separation of a mixture of substituted naphthalenes was developed. Since a silica column was used, the modifiers were chosen from the “localization” inner triangle: MTBE (basic localizing),
acetonitrile (nonbasic localizing) and methylene chloride (nonlocalizing). Initial experiments indicated that a 42% : 58% hexane–methylene chloride mixture yielded the appropriate solvent strength. This solvent mixture was then used for the first isocratic experiment. Subsequent experiments with 96 : 4 hexane–MTBE and 87 : 10 : 3 hexane–methylene chloride–acetonitrile followed. Note that the third mixture required methylene chloride as a co-solvent for hexane and acetonitrile. Experiment 4 mixed the mobile phases used in experiments 1 and 2: 77 : 22 : 1 hexane–methylene chloride–MTBE. Similarly, experiment 5 mixed the mobile phases used in experiments 2 and 3 (92 : 5 : 2 : 2 hexane–methylene chloride–MTBE–acetonitrile), while experiment 6 mixed the mobile phases from experiments 1 and 3 (69 : 30 : 1 hexane–methylene chloride–acetonitrile). Finally, experiment 7 mixed all three binary mobile phases used in the initial three experiments: 89 : 9 : 1 : 1 hexane–methylene chloride–MTBE–acetonitrile.

5.2 Stationary Phase Choices

The introduction of bonded phases for use in NPLC allows stationary phase optimization in parallel with mobile phase optimization. It has been suggested that the cyano, amino and diol columns represent a stationary phase selectivity triangle. Not only do these columns provide different retention characteristics, they also can induce very significant and unique secondary solvent effects due to preferential adsorption of mobile phase modifiers. Thus, for particularly challenging separations, mobile phase optimizations superimposed on changes in stationary phase selectivity may be required. Figure 5 demonstrates how a change in column alone (silica to a diol bonded phase) can provide adequate separation of a mixture of phenols. Figure 5 also points out the dramatic changes in solvent strength of modifiers – in this case methanol – when used with different stationary phases.

6 TECHNIQUES

6.1 Isocratic Separations

Isocratic separations utilize a single mobile phase composition to elute sample components, in contrast to gradient elution where the mobile phase composition is changed during the course of a separation. The overwhelming majority of LC separations are done isocratically, which is preferred for a number of reasons. First, most mobile phase solvents are not completely transparent to spectroscopic detectors and thus changes in mobile phase composition produce detector “drift”. In addition, after a gradient elution separation is completed the mobile phase composition must be returned to its original value. This is not as simple as might seem, since the column must also be re-equilibrated with the original solvent mixture, a time- and solvent-consuming procedure.

The introduction of bonded phases for use in the normal-phase mode has greatly increased the opportunities for isocratic NPLC separations. With judicious solvent and/or stationary phase optimization, most sample mixtures can be adequately resolved with a single mobile–stationary phase combination. In addition, many of the benefits of gradient elution can be realized using the column switching and stationary-phase programming techniques discussed below.

6.2 Gradient Elution

In spite of the most exhaustive isocratic optimization efforts, some samples are so complex and contain solutes with such a wide range of sample capacity factors at any mobile phase composition that gradient elution is required. This is known as the “general elution problem”. At some intermediate value of solvent strength there is insufficient resolution of early-eluting peaks, with extremely long retention of later-eluting peaks. Decreasing solvent strength can increase resolution of the early-eluting peaks, but the result is unacceptably long retention times of the rest of the sample mixture components. Conversely, the strongly-retained solutes can be eluted in a reasonable time by increasing the mobile phase solvent strength, but at the expense of the resolution of the early peaks.
The solution to this general elution problem is to change the capacity factors of solutes during the course of a separation by changing mobile phase composition. This is normally accomplished by using a binary mixture of a weak and strong solvent and increasing the relative proportion of strong solvent as the chromatogram proceeds. A gradient elution separation thus begins with a weak binary solvent mixture that yields capacity factors for early peaks which are sufficiently high for the necessary resolution. Later peaks clearly have capacity factors which are very large and they do not move very far down the column in the first stages of the gradient. However, as the mobile phase increases in strength, the capacity factors of more strongly-retained compounds decrease to the point that they begin to move and eventually elute from the column.

There are a number of very positive benefits that result from gradient elution. The first and most obvious is that a wide range of solutes differing greatly in molecular properties can be separated in a single chromatogram. In addition, since the movement of any solute through the column is significant only when some minimum capacity factor has been reached, most solutes experience roughly the same “average” capacity factor during their elution. This means that solute bands elute with approximately equal peak widths. Finally, the gradient elution procedure actually produces a gradient of mobile phase solvent strengths along the column. This means that the back side, or tail, of a solute band will be in a stronger solvent environment than the front. This effect tends to sharpen the bands of polar, strongly-retained solutes which would otherwise be broad due to specific interactions with the stationary phase surface. This last feature of gradient elution is particularly useful in NPLC because of the polar stationary phases commonly used.

There are two important considerations when developing a gradient separation: the shape of the gradient and the rate at which the solvent strength of the mobile phase is changed. The most common gradients are depicted in Figure 6. Note that the gradient is usually defined in terms of the change in the amount of strong (B) solvent in the mobile phase. Linear gradients are the most popular, but modern liquid chromatographs are capable of producing a variety of alternative gradients. A convex gradient, which produces a slower rate of change of mobile phase composition at the end of the chromatogram, may be called for if a linear gradient produces adequate resolution of early-eluting peaks but inadequate resolution of later peaks. This situation is sometimes encountered in environmental and petroleum applications when, for example, polynuclear aromatic hydrocarbons are separated by both number of rings and then number of substituents on each ring. Because the number of possible substituents increases with number of aromatic rings, greater resolution is actually needed at the end of the chromatogram, not the beginning.

Of more interest in NPLC are concave gradients in which the rate of change of mobile phase composition is slower in the early stages of the chromatogram, increasing as the chromatogram develops. This type of gradient is often more appropriate for NPLC because of the nonlinear relationship between solvent strength and % modifier (Equation 7). Such a gradient comes much closer to producing a gradient that is linear in solvent strength.

In addition to choosing a gradient type, the optimum rate at which mobile phase composition is changed must be determined. The rate at which the strong modifier is added to the mobile phase is referred to as the gradient steepness and is normally expressed as Δ%B min⁻¹. In the linear gradient depicted in Figure 6 the modifier content changes from 10% to 50% over a period of 20 min: a gradient steepness of 2% min⁻¹. Because different modifiers have different pure solvent strengths, they thus produce different solvent strength gradients at fixed steepnesses. Determining the optimum gradient steepness for a particular gradient elution separation normally requires a trial-and-error approach, although Snyder, Kirkland and Glach have provided some guidelines.

One final word about gradients is necessary and is suggested in Figure 6, where none of the gradients begin at 0% B. Because the polar modifiers in NPLC are preferentially adsorbed by nonpolar stationary phases, the first exposure of the stationary phase to the modifier normally produces a rather significant imbalance in mobile and stationary phase concentrations of B. This will continue until the stationary phase is saturated with B such that the proper equilibrium of B between mobile and stationary phases is reached. Furthermore, this imbalance

![Figure 6 Typical gradients used in HPLC.](https://example.com/image.png)
is most pronounced at very low (<1–5% B) modifier contents. Thus, to produce “smooth” gradients, it is always advisable to begin the gradient at some fixed level of modifier in order to saturate the stationary phase.

6.3 Column Switching, Stationary Phase Programming, and Two-dimensional Liquid Chromatography

For all of its advantages, gradient elution LC does have some drawbacks, as noted previously. These drawbacks have led to an interest in exploiting changes in stationary phase strength and selectivity to accomplish the same chromatographic effect produced by gradient elution. Again, the fundamental principal involved is changing the capacity factors of solutes during the chromatogram. NPLC has the advantage over RPLC in this regard because of the ability to change retention mechanisms by changing columns. This is not routinely possible in RPLC where hydrophobic forces dominate retention in all columns.

Column switching refers to the use of multiple chromatographic columns and switching valves to optimize the separation of very complex mixtures. It is a routine practice in gas chromatography and is finding increasing popularity for LC separations. The fundamental advantage of using multiple columns in this way is that isocratic mobile phases can be employed.

Stationary phase programming is one of the most useful forms of column switching and is analogous to gradient elution. It is normally accomplished by combining columns of different retentive strength or activity with a switching valve. The first column has a significantly lower activity than the second. A sample mixture is injected into the first column and rapidly-moving bands made up of nonpolar components are not separated by this first column but are diverted by the switching valve to the second. Once these fast-moving bands have been loaded onto the second column, the valve is switched so that the slower-moving, more strongly retained solutes, which in principal will be separated by the first column, are directed to the detector. After detection of this first set of polar compounds, the valve is returned to its original position, directing solvent back through column 2. The first, less-polar group of solutes is then eluted. Thus, the retention order of solutes 1–6, where 1 was the least polar and 6 the most polar, might be:

\[ 4 < 5 < 6 \ll 1 < 2 < 3 \]

A column switching technique that is more powerful than stationary phase programming and which is made available by the unique characteristics of different NBP columns is two-dimensional (2-D) chromatography. 2-D chromatography is normally thought of as involving sample displacement (elution) in two dimensions that are physically orthogonal to each other. However, if the two displacements are also chemically orthogonal, then the maximum amount of separation space is available. When the two displacements are physically orthogonal the total peak capacity of the system (the maximum number of peaks that can be resolved in a given time window) is the sum of the individual peak capacities of each displacement (Equation 8).

\[ n_T = n_1 + n_2 \]  

(8)

However, when the two displacements are also chemically orthogonal, the overall peak capacity of the system approaches the product of the individual peak capacities (Equation 9).²³

\[ n_T = n_1 n_2 \]  

(9)

Figure 7 is a schematic representation of a serially coupled NPLC system that can be used to achieve such 2-D separations.²⁴ The system uses two bonded phase columns that had previously demonstrated different retention selectivities.⁹ It also includes two six-port valves. In the “load loop 1” position, loading valve L directs effluent from column 1 to sampling loop 1 while at the same time pumping solvent 2 through loop 2 and into the injection valve I. The injection valve I simply directs effluent from loop 1 to waste and solvent 2 through column 2 and detector 2. Here, solvents 1 and 2 are identical. Once the appropriate peak(s) have been loaded in loop 1, the load and injector valves are rotated and the loop–column configurations reversed. Loop 2 is now being filled with the effluent from column 1 while the contents of loop 1 are injected onto column 2.

Figure 8 contains the resulting 1-D (one-dimensional) and 2-D chromatograms using an identical 70 : 30 (v/v)

LIQUID CHROMATOGRAPHY

7 APPLICATIONS

Following are some examples of separation problems that are uniquely suited to NPLC. NPLC is particularly useful in the environmental, biomedical and pharmaceutical fields, since many analytical procedures in these areas begin with extraction of solutes from a polar matrix into a lipophilic solvent. One of the major advantages of NPLC over RPLC is that a solvent changeover is not necessary after such an extraction. For RPLC analyses, solutes in the lipophilic extract must be moved to a polar solvent suitable for the reversed-phase mode.

7.1 Isomers

As noted in the Introduction, NPLC is the preferred mode for separating achiral isomers. The ability of isomeric molecules containing multiple polar substituents to interact with the fixed absorption sites on NPLC columns and experience localization/delocalization effects depends on the geometry of molecules and the positions of the polar groups. Figure 9 provides a dramatic example of the superior effectiveness of NPLC over RPLC for separating a series of retinol isomers.\(^{[25]}\)

7.2 Environmental

The analysis of environmental contaminants in water, soils and foodstuffs is now one of the most common procedures carried out by regulatory agencies.
Many of these contaminants are only sparingly soluble in water and are thus extracted from environmental matrices with hydrophobic organic solvents. Resolution of individual components in these extracts is facilitated if the extract can be transferred directly to the separation column. This makes NPLC very attractive for such analyses since these lipophilic extraction solvents are normally compatible with NPLC solvents. Indeed, there are now many descriptions in the literature of automated, on-line extraction and LC separation systems.

Figure 10 demonstrates just such a combination of lipophilic extraction and NPLC for environmental purposes. The nonionic surfactant mixture Triton-X-100 was extracted from water onto a solid-phase microextraction fiber, then desorbed with 97:3 (v/v) hexane–isopropanol. The Triton-X mixture in that extract was then separated by gradient elution NPLC using an amino column. The wide range of molecular weights in this Triton-X mixture is a common feature of samples that require gradient elution techniques.

### 7.3 Biomedical and Pharmaceutical

There are many molecules of biological and pharmaceutical interest that are not only lipophilic, but also require separations based on subtle structural features which are most easily distinguished by NPLC. Fat-soluble vitamins are a good example, since it is very difficult if not impossible to get them dispersed in a reversed-phase solvent. Figures 11 and 12 demonstrate the utility of a normal-phase amino column for such separations. In Figure 11 various tocopherols (Vitamin D) are easily resolved in less than 10 minutes isocratically. The strength of NPLC for isomer separations is further demonstrated in the chromatogram in Figure 12 in which Vitamin K isomers are cleanly resolved.

While RPLC is normally the choice for separating and purifying peptide mixtures, it is not always the best choice...
for hydrophilic peptides. Such peptides can frequently be better separated using special normal-phase columns and aqueous-based mobile phases. Figure 13 contains chromatograms of a mixture of peptides separated on reversed-phase and normal-phase TSK® gel columns. The TSK®-Amide normal-phase column clearly provides better resolution and efficiency in less time than the TSK®-ODS reversed-phase column.

Reversed-phase liquid chromatography (RPLC) is an elution procedure used in liquid chromatography (LC) in which the mobile phase is significantly more polar than the stationary phase, e.g. a microporous silica-based material with chemically bonded alkyl chains. Typically, the mobile phase is a mixture of an aqueous component, often containing a buffer to control pH, and a water-miscible polar organic solvent and the stationary phase is an alkyl derivatized silica (see Silica Gel and its Derivatization for Liquid Chromatography).

RPLC was first developed in the mid- to late-1970s as a direct consequence of needs arising from the shortcomings of normal phase LC. Normal phase LC itself utilizing adsorption chromatography had been an advance on partition chromatography. It might not have preceded RPLC had it not been for the fact that polar materials such as silica and alumina could be produced as porous microparticles while at the time there were no materials available readily to prepare nonpolar porous microparticles. However this situation had to be addressed as the aforementioned shortcomings of normal phase LC became more apparent (see Silica Gel and its Derivatization for Liquid Chromatography):

- The silica surface was heterogeneous, containing acidic isolated silanol groups, H-bonded silanol groups, geminal silanol groups, relatively nonpolar Si-O-Si bonds, metal impurity activated silanol groups, ion-exchange Si-O⁻ sites and adsorbed water; this could give rise to poor efficiency arising from mixed retention mechanisms or at worst very bad peak tailing for basic compounds caused by interaction with the more strongly acidic sites.

- Polar analytes could have very long retention times or, even worse, not be soluble in the mobile phase.

The latter issue was the most telling since much of the momentum for the development of LC was provided by the necessity to analyze drugs in a rapidly expanding pharmaceutical industry. Since drugs must get into the body, which contains a substantial proportion of water, they generally tend to be polar ionizable compounds. Further, they are often presented as salts or in aqueous solutions. Accordingly it became essential that suitable nonpolar stationary phases should be developed in order that polar mobile phases might be used.

In the early days of RPLC the market was dominated by columns packed with Waters’ C₁₈-µBondapak, a 10-µm irregular material in which residual silanol groups had not been end-capped (see Silica Gel and its Derivatization for Liquid Chromatography). This material enjoyed enduring commercial success but stationary-phase technology soon progressed to the point in the early 1980s that 5-µm spherical end-capped silica materials with a narrow particle size range were the norm. This was still very much the case in the mid-1990s despite a number of subsequent useful developments in the intervening period, including the advent of 3-µm particles, base-deactivated silicas and more stable protected C₁₈ materials (sections 3.4 and 4). Similarly there have been many exciting developments in
miniaturized LC but in a typical routine quality control laboratory the only concession to saving on solvent use and shortening run times might be the use of a 10-cm or 15-cm column rather than a 25-cm column and only occasionally the use of a 2-mm or 3-mm rather than 4.6-mm inner diameter (ID) column diameter.

A system that would be fairly characteristic of the usual practice of RPLC would therefore be a $150 \times 4.6$-mm ID stainless steel column packed with a bed of 5-µm spherical C$_{18}$ porous microparticles with a narrow particle size range using a mobile phase of methanol and an aqueous phosphate buffer. While there are several organic solvents that might be used as alternatives to methanol, most can be ruled out on the grounds of high cost, high toxicity, high viscosity or not being transparent to the detector, usually ultraviolet (UV), being used. Therefore acetonitrile is the only other frequently used organic component of the mobile phase. Tetrahydrofuran (THF) is also used but usually in proportions in the order of 5–20% along with acetonitrile or methanol in order to "fine tune" selectivity. Phosphate is a popular buffer because it controls pH well over a wide part (2.5–4.5 and 6.5–7.5) of the pH range between 2.5–7.5 over which silica-based columns are usually considered to be stable. The main disadvantage of its use is that the inorganic salt can precipitate out of the mobile phase if the proportion of the organic component is too high. This is particularly a problem for acetonitrile. Its other disadvantage is that it is not volatile. This is becoming much more of an issue with the increasing use of mass spectrometric detection in LC. Even if an assay is being developed for use with UV detection, mass spectrometry (MS) compatibility might still have to be borne in mind since it might become necessary to use MS to identify peaks of unknown identity in the chromatograms obtained. As the instrumentation required to carry out isocratic LC is simpler than that required to carry out gradient LC (see Gradient Elution Chromatography) every effort will usually be made to develop isocratic RPLC methods. However for some analyses of complex mixtures in which the compounds present have a wide range of polarities, the use of gradient RPLC may be unavoidable. The determination of structurally related impurities in a drug substance is one such example.

It has already been stated that the desirability of being able to dissolve polar analytes in a polar mobile phase was one of the driving forces for the development of RPLC. This remains one of the main advantages of RPLC. Nonetheless it should not be overlooked that it also has the advantage of being applicable to the analysis of compounds having a very wide range of polarities. The other main advantage is the number of variables that can be used to manipulate selectivity and retention to achieve a desired chromatographic resolution. These advantages together account for the fact that RPLC is so versatile and effective that it is used for a very large proportion of all LC analyses.

The disadvantages of RPLC are few indeed. There are not too many analyte classes for which another mode of chromatography is needed in order to obtain a separation that could not be obtained by RPLC. There are also only a few instances where RPLC is not used for other reasons of a more practical nature. For example wide pore packing materials may be used to carry out RPLC of proteins but another mode of chromatography will frequently be preferred to RPLC because of the danger of the proteins being denatured by the stationary phase or the presence of too high a concentration of the organic component of the mobile phase.

2 THEORY AND RETENTION MECHANISM

Like most other modes of chromatography, retention in RPLC may be described by either a solvent interaction model or a solvent competition model. However it is most commonly interpreted by the application of solvophobic theory which borrows elements from both the solvent interaction and the solvent competition model. The stationary phase is regarded as being saturated with molecules of the organic component, i.e. the most strongly eluting component of the mobile phase. Retention by the stationary phase arises from repulsion of hydrophobic regions of the analyte molecule by the water molecules which "drives" the analyte onto the stationary phase or at least into the layer of the organic component adsorbed on its surface (Figure 1). The extent to which the situation resembles the solvent interaction or solvent competition

![Figure 1](image-url)
model might depend on the extent to which this hydrophobic repulsion is moderated by specific analyte–organic solvent or analyte–stationary phase interactions. The frequency with which these are a significant influence is discussed later (sections 3.4 and 3.5).

However, since retention is mainly related to analyte hydrophobicity, the 1-octanol–water partition coefficient (log \( P \)), or more particularly \( \log \text{P}_{\text{app}} \) (where \( \text{P}_{\text{app}} \) is the distribution coefficient at a particular pH or apparent partition coefficient; it will be less than \( P \) if some of the analyte is ionized at the pH in question) to take into account the degree of ionization at the mobile phase pH, of the analyte can be used either qualitatively or quantitatively to assess how well an analyte will be retained. Similarly in attempting to rationalize the effect experimental variables have on retention it is helpful to think in terms of how a change in the mobile phase will affect the proportion of water molecules in the mobile phase and thereby how its capacity to “accept” analyte molecules is affected.

### 3 EXPERIMENTAL VARIABLES

#### 3.1 Chromatographic Resolution

The whole point of separative methods is to obtain specificity in an analytical method by resolving the analyte from all other detectable components of the sample being analyzed. In RPLC, as with other modes of LC, chromatographic resolution depends on efficiency, retention and selectivity. Equations (1–5):

\[
\begin{align*}
\text{Efficiency, } N &= 16 \left( \frac{t_r}{w_b} \right)^2 \\
\text{Capacity factor, } k' &= \frac{t_r - t_0}{t_0} \\
\text{Selectivity, } \alpha &= \frac{k_2'}{k_1'} \\
\text{Resolution, } R_s &= \frac{t_{r2} - t_{r1}}{0.5(w_{x2} + w_{x1})} \\
R_s &= \frac{1}{4} \sqrt{N} \cdot \frac{\alpha - 1}{\alpha} \cdot \frac{k_1'}{k_1' + 1}
\end{align*}
\]

where \( t_r \) is the retention time for peak x (r is peak number, e.g. 0 for unretained, 1 for first, 2 for second etc.), \( t_0 \) is the retention time for an unretained analyte and \( w_{bx} \) is the baseline width for peak \( x \); all of these must be measured in the same units.

Given the general use of 5-µm particles, for good reasons, for example the practical problems associated with the use of particles with lower diameter than this and the fact that there is a square root dependency of resolution on efficiency (Equation 5), means that there is less incentive to overcome these practical problems, and column efficiency is not often used as a variable to improve resolution. Occasionally a chromatographic method may involve operation at elevated temperature, with faster mass transfer resulting in improved efficiency. However the exploitation of elevated temperature in RPLC is more likely to involve simply thermostating at 5°C or more above ambient temperature in order to allow strict control of temperature for reproducible chromatography.

Most of the variables in RPLC affect retention but changes in retention have limited value in improving resolution because (i) an increase in run time is not desirable under normal circumstances, (ii) above \( k' \sim 4 \) increases in retention have limited effectiveness in improving resolution (Figure 2), and (iii) most importantly, most of the variables which change the retention of one sample component will change the retention of all the other components in the same direction (section 3.3). Having said this, it is apparent from Figure 2 that for analytes with \( k' \) in the range 0–2, an increase in \( k' \) will be highly effective in bringing about an improvement in resolution.

By a process of elimination it should be apparent that improving selectivity is the most useful means of improving resolution and this is indeed the case (Figure 3). The fact that increasing selectivity is not so effective for increasing resolution when selectivity is already greater than \( \sim 2 \) is of little consequence.
LIQUID CHROMATOGRAPHY

because in this range separations would be very easy to achieve in any case. It has already been stated that most of the variables which change the retention of one sample component will change the retention of all the other components in the same direction. Clearly, to improve selectivity it would be best to use an experimental variable that gave rise to increases in retention for some analytes and decreases in retention for others. This is why the use of changes in mobile phase pH is so important in RPLC method development.

3.2 Selectivity Manipulation Using Mobile Phase pH

pH control is very important in RPLC of ionizable compounds, Equation (6) for acids and Equation (7) for bases:

Acids

\[
\text{RH} \iff \text{R}^- + \text{H}^+ \quad (6)
\]

(sulfonic acids, carboxylic acids, phenols, coumarins, sulfonamides, barbiturates, \(\beta\)-diketones, etc.)

Bases

\[
\text{RH}^+ \iff \text{R} + \text{H}^+ \quad (7)
\]

(amines)

Irrespective of retention and selectivity issues, it is important that the mobile phase pH is such that an ionizable analyte is either fully ionized or fully un-ionized. For anything in between this situation, if the ionization/deionization rates are not rapid on the chromatographic timescale then chromatographic efficiency will be reduced, possibly accompanied by the development of peak asymmetry. Even if the equilibrium is rapidly reversible, problems might arise. A slight change in the preparation of the mobile phase might introduce a slight change in pH which would bring about a slight change in the position of the equilibrium and thereby a shift in retention. In other words an analytical method based on such chromatography would not be robust.

The decision on whether the ionizable analyte should be chromatographed in its fully ionized form or its fully un-ionized form depends on whether it is required for the analyte to be well retained or otherwise. Clearly the ionized form, being charged, will be the more polar form (Equations 6 and 7). Being more polar it will be less repelled by water molecules and therefore less well retained in RPLC. Accordingly if it is required to reduce the retention of an acid, the mobile phase pH must be increased. Similarly if it is required to reduce the retention of a base, the mobile phase pH must be decreased. The fact that a pH change will affect the retention of an acid and a base in the opposite direction is the reason why it is the most important variable in RPLC method development in the sense that it is able to bring about a change in selectivity.

It is necessary then in RPLC method development to be aware of the pH values at which an analyte will be fully ionized or un-ionized. The degree of ionization of an ionizable analyte at a particular pH may be determined by the well-known Henderson–Hasselbach equation, Equations (8) and (9):

\[
\% \text{ Ionized acid} = \frac{100}{1 + \text{anti} \log(pK_a - \text{pH})} \quad (8)
\]

\[
\% \text{ Ionized base} = \frac{100}{1 + \text{anti} \log(pH - pK_a)} \quad (9)
\]

This can be simplified for the situation when the analyte is 50% ionized and so on for 90%, 99%, to develop a so-called “rule of thumb”, see Table 1.

Therefore for an ionizable analyte to be fully ionized or fully un-ionized the mobile phase pH must be at least three pH units higher or lower than the pK_a of the analyte. While the pK_a of the analyte may be measured, there is a need to know the pK_a of all the other sample components because they will have to be resolved from the analyte. As it is impractical to carry out pK_a measurements for all sample components, it is vital in RPLC for the analyst to be able to recognise functional groups in an analyte and to be aware of their likely pK_a values. This is very much the case, for example, in the analysis of drugs. As has already been stated (section 1), compounds of pharmaceutical interest are usually polar and ionizable.

### 3.3 Control of Retention

While the manipulation of pH is invaluable with respect to improving selectivity between ionized and un-ionized analytes, the role of other experimental variables in changing retention should not to be underestimated. As has been observed (Figure 2), increasing retention is very effective for increasing resolution when \( k' < 2 \). At higher retention, increasing retention is a less effective means of improving resolution and in any case it would not be advisable to go on increasing analysis time when it is already excessive.

The effect on \( k' \) of changing various experimental variables is shown in Table 2. These effects can be rationalized by the solvophobic theory. For example by increasing the proportion of methanol in the mobile phase or switching from methanol to acetonitrile the mobile phase is made less polar. Being more hydrophobic it is less likely to give rise to repulsion of a hydrophobic region.

DMOA (N,N-dimethyloctylamine) is a “masking agent” introduced into the mobile phase at levels of ~0.0005 M to prevent the interactions between basic analytes and residual silanol groups on the stationary phase which lead to peak tailing.

of the analyte and “drive” it onto the stationary phase. Hence the mobile phase is more strongly eluting and $k'$ is reduced. This holds so long as there is a “pure” reversed-phase retention mechanism based on hydrophobicity and there are no specific analyte–solvent interactions. Methanol can take part in hydrogen-bonding interactions, acetonitrile can take part in dipole–dipole interactions and THF can act as an electron pair donor. If such interactions between solvent and analyte take place they will hold up the analyte in the mobile phase more than would be the case and hence give rise to a reduced retention time.

It is perhaps less clear on the basis of solvophobic theory why alkyl-bonded silica phases with longer alkyl chains are more retentive. The greater the “carbon loading” of the stationary phase the greater will be its capacity at saturation for the organic component of the mobile phase. Effectively then the stationary phase has a greater “volume” and is therefore more retentive.

The effect of masking agents such as DMOA (see Silica Gel and its Derivatization for Liquid Chromatography) on retention has been less of a concern because they are being used less with the increasing use of base-deactivated silaceous reversed-phase packing materials. However it remains an issue since many methods that were developed years ago are still in use. The interactions of basic analytes with residual silanols that the masking agent is designed to block contribute to the overall degree of retention. Therefore when the blocking takes place, $k'$ is reduced. Generally silanol interactions do not contribute significantly to the retention of neutral and acidic analytes. However, acidic analytes in their ionized form may enter into a hydrophobic ion-pair with net zero charge with the masking agent and hence be more retained.

While changes in flow rate and column length affect retention time they clearly do not affect $k$, as the elution time of an unretained analyte would be changed in the same way. Any changes to resolution that they bring about will arise from their effect on column efficiency.

3.4 Stationary Phase Selectivity

As mentioned already in the context of the use of masking agents and the occurrence of solvent–analyte interactions, the retention mechanism in RPLC will not always be exclusively based on hydrophobicity. The most common additional contribution to retention from stationary phases is that from the interaction of basic analytes with residual silanol groups on the stationary phase, this being more of a problem for more acidic isolated silanol groups or those activated by the presence of metallic impurities than for silanols which are H-bonded to neighboring silanols. While these interactions affect peak shape and retention of basic analytes they would not have a profound effect on the selectivity exhibited towards a series of basic analytes. The same may be said for stationary phase specific interactions exhibited by functional groups (e.g. cyano-, phenyl-, diol, nitro-) present in medium polarity RPLC stationary phases. Studies with a wide range of model analytes have suggested that retention orders correlate fairly well with those found on alkyl-bonded silicas.

Retention in the few stationary phases that are not silica-based is also dependent on hydrophobicity. This is especially the case for the styrene–divinylbenzene copolymer (PRP-1) (Scheme 1). There appear to be no specific interreactions with the aromatic rings on the stationary phase surface and the degree of correlation between retention and hydrophobicity is such that log $k'$ values may be used as a measure of analyte partition coefficients.

![Scheme 1 Preparation of PRP-1.](image-url)
Another nonsilaceous packing material for RPLC is the porous graphitic carbon phase, Hypercarb®. Like PRP-1, Hypercarb® can be used at extremes of pH and is more retentive than octadecylsilyl silicas. In fact it is much more retentive even than PRP-1 and this is a property that may be usefully exploited. A good illustration of this is the use of Hypercarb® in microbore LC columns. One of the advantages of microbore LC is that it may be used to obtain increased mass sensitivity. However, gains in this direction are compromised by extra-column band-broadening effects arising in particular from the injection volume. As Hypercarb® is so retentive it is an easy matter to find a weakly eluting solvent for the sample solution so that when large volumes of sample solution are injected onto the column an on-column sample focusing effect takes place.

While the fact that Hypercarb® is highly retentive and may be used at extremes of pH is of interest, what really sets this material apart is its unique selectivity. Hydrophobicity has an influence on retention but there is a strong contribution from π-stacking effects and there is often strong retention of rigid planar analyte molecules which are able to interact strongly with the flat planar graphite surface (Figure 4). Accordingly Hypercarb® is the only material used in RPLC that has sufficiently different selectivity from that of alkyl-bonded silicas for it to be claimed to have “orthogonal” selectivity from such phases.

### 3.5 Mobile Phase Optimization

As retention in RPLC is so dependent on hydrophobicity of the analyte, mobile phase and stationary phase, method development in RPLC ought to be fairly simple with retention times of analytes being fairly easy to predict. The issue of course is complicated by the contributions to retention of specific solvent and stationary phase interactions which are difficult to predict a priori. Therefore, rather than using expert systems which use information on analyte, stationary phase and mobile phase properties, it is much more common to choose a column likely to be suitable for the analyte and to carry out computer-aided automated mobile phase optimization in which predictions are based on a few initial experiments with the mobile phase conditions then being refined. One of the most popular packages used for RPLC method development is DryLab in which isocratic and gradient conditions are predicted on the basis of just two initial experiments which are usually gradient runs. This allows the analyst quickly to arrive at suitable mobile phase conditions under which the analytes have the desired retention times. There is a range of more sophisticated software packages available which are designed to work in conjunction with a specific manufacturer’s instrumentation to allow totally unattended fine tuning of the separation.

![Figure 4 Structure (a), surface cross-section (b) and plan-view (c) of the porous graphitic carbon stationary phase, Hypercarb®.](image)
4 PERSPECTIVE AND FUTURE DEVELOPMENTS

Despite the availability of other modes of LC and alternative techniques such as capillary electrophoresis and capillary electrochromatography, RPLC will continue to be the most frequently used means of carrying out a separative method for the foreseeable future. It is versatile, provides adequate resolution and convenient conditions for the vast majority of applications and, most importantly, because there are vast sums of money invested into the use of RPLC, it will not be replaced until the unlikely event of a new LC mode or alternative technique coming along which is significantly better than RPLC across the board.

Developments in new stationary phases will continue but already much has been done to exploit materials other than silica and to produce silica-based phases which are usable over a wider pH range and/or may be made more reproducible and/or give much reduced peak tailing with basic analytes. As for other modes of LC there will be further moves in RPLC towards the use of columns with reduced dimensions. This is because economic and environmental considerations are now more important. Also, with the increasing use of mass spectrometric detection for RPLC there is less need for complete resolution of all peaks so that it is possible to use shorter columns with faster flow rates for increased sample throughput. One of the main advantages of RPLC is that it may be used for a wide range of analyte polarities. However this often leads to the necessity for solvent gradient methods when the sample is a complex mixture containing analytes with very different polarities. This requires more sophisticated instrumentation and usually involves long analysis times even not allowing for the time required for the column to be reconditioned with the starting mobile phase. The elimination of such lengthy procedures is one of the few remaining research targets in RPLC.

Silica Gel and its Derivatization for Liquid Chromatography

Uwe D. Neue
Waters Corporation, Milford, MA, USA

1 INTRODUCTION

Bonded phases based on silica gel as well as other silica derivatives constitute the most widely used stationary phases in high-performance liquid chromatography (HPLC). On one hand, this is due to the superior hardness of silica compared with organic gels, which enables the use of the high pressures required to achieve high resolving power at short analysis times. On the other hand, the ability to modify the surface of silica via silanization has contributed significantly to its widespread applicability. While the chemical stability of zirconia or titania is significantly better than that of silica, the surface chemistry of these oxides is more complicated and cannot be manipulated as easily as the surface chemistry of silica. Therefore, the true secret of the success of silica lies in the silanization chemistry.

In this article, the physical and chemical properties of silicas used as sorbents in HPLC will be reviewed first. This discussion includes a brief description of the newer technologies such as nonporous particles and continuous rods. Then silica-based bonded phases will be described in substantial detail: preparation techniques, properties of the bonded phases and general characterization techniques, and the properties and use of specific bonded phases. Owing to the widespread use of reversed-phase chromatography, most of this section is dedicated to C18 and C8 bonded phases; however, we will not neglect specific topics such as special phases designed for carbohydrate separations or protein separations. The final section is dedicated to phases that are coated onto silica. These phases may or may not be attached to the silica surface. We will review the preparation techniques as well as the properties of these phases. It should be noted that some of the stationary phases of this type can also be prepared on other inorganic carriers, but a wider discussion is outside the scope of this article.

2 PROPERTIES OF SILICA

What are the properties of silica that make it desirable for use as a sorbent in HPLC? Chromatographic retention is proportional to the ratio of accessible surface area to packed bed volume. In addition, the amount of analyte that can be injected onto a column is also a function of the surface area in a column. Since the analysis should be insensitive to the amount injected onto a column, the surface area of a packing should be maximized. To achieve a maximum ratio of surface area to volume, the packing should be porous. However, the surface needs to be accessible to the analytes of interest, which puts a lower limit on the pore size and an upper limit on the specific surface area of a packing. The freedom in the manipulation of pore size and surface area is one of the strengths of silica.

In contrast to sorbents based on an organic backbone, silica does not swell nor shrink depending on the solvent in
which it is used. Physical properties such as pore volume, pore size distribution and surface area are permanent properties of the packing. Similarly, the permeability of a packed bed is independent of the solvent used. Both effects represent significant advantages in the solvent compatibility of silica-based packings compared with organic polymeric packings. The hardness of the packings also allows the use of higher pressures and smaller particle sizes than are possible with organic polymeric packings.

The third distinguishing property of silica is the ease of modification of the surface using silanization techniques. Silanization allows the design of “reversed” phases and many other bonded phases that modify the properties of the native silica substantially and therefore enable specific separation techniques that are not possible with other packings. Most of the discussion in this article is dedicated to the description of the surface modification of silica.

In the following paragraphs, the physical properties of silica and packed beds are first discussed in more detail. Then the chemical properties of silica are examined.

2.1 Preparation of Porous Silicas

In order to frame this discussion, we will start with a brief review of the preparation of porous silica.\(^1\) The common starting point in the preparation is a silicic acid monomer, such as sodium silicate or one of the silicic acid esters, such as tetramethoxysilane. These monomers are polymerized to a specific molecular weight or size. This prepolymerized silica, which may be in the form of a sol, is then further agglomerated to form the final particles. The agglomeration is carried out in the presence of porogens, which are additives that are used to influence the specific pore volume and, together with the size distribution of the prepolymerized sol, the pore size distribution of the silica. In all modern preparation techniques for HPLC-grade silica, spherical particles are generated in this process. The most commonly used technique for the preparation of the silica particles is suspension polymerization, but a spray drying process can be employed as well. The type and purity of the raw materials significantly influence the properties of the chromatographic sorbent. This will be discussed in more detail in section 2.3 which discusses chemical properties of silica, and section 3.5.2 which covers the chromatographic tests for the properties of reversed-phase bonded phases.

The retentive properties of a silica for specific analytes depend on the access of the analytes to its surface and therefore on its pore size distribution. The pore size distribution of a silica prepared in the manner described above depends on the size distribution of the primary silica sol and the specific pore volume. If one wants to change the average pore size of a packing, two techniques are available. The first technique is manipulation of the average size of the sol before preparation of the silica particle. The second is the use of an Ostwald ripening technique to increase the size of the structural units that form the backbone of the silica particle. This second technique is employed after preparation of the particle and is mostly utilized in the production of silica gels with a large pore size, which are commonly used for the chromatography of high-molecular-weight compounds such as polymers and biopolymers. In this technique the silica is subjected to elevated temperature and pressure in the presence of water in an autoclave to achieve the desired pore size distribution. Under these conditions, both the structure of the silica backbone and the pores grow in size. Additionally, if carried out properly, the pore volume remains largely unaffected. Silicas prepared by both techniques can be distinguished easily microscopically (Figures 1 and 2).

2.2 Physical Properties of Silicas

2.2.1 Pore Size, Pore Volume, Surface Area

The pore size distribution, pore volume and surface area are the physical characteristics of a silica that are responsible for its retention properties. Porous silicas used for the chromatography of small molecules have an average pore size of around 10 nm (commonly 5 nm to 15 nm) and a specific surface area between 100 m\(^2\) g\(^{-1}\) and 400 m\(^2\) g\(^{-1}\). Silicas with an average pore size smaller than about 5 nm exhibit restriction to mass transfer in the pores for typical analytes. As a result, chromatographic peaks are broader than they should be. Silicas with a
Figure 2  Silica prepared using Ostwald ripening for pore enlargement. The structure reminiscent of corals is typical for a pore-enlarged silica. Material: Nucleosil® 4000–7 (Macherey-Nagel, Germany).

Significantly larger pore size have a smaller surface area and therefore less retention for typical analytes. However, as the molecular weight of the analyte increases, the pore size of the most appropriate packing increases as well. The chromatography of proteins is commonly carried out using silicas with an average pore size of 30 nm or more.

The specific surface area and the specific pore volume are the respective values normalized per gram of packing. They are commonly reported in the manufacturers’ literature. While the surface area of a packing is responsible for the retention, it should not be assumed that the retentivity of a silica is proportional to the surface area alone. It should be remembered that the retentivity of a silica is determined by the phase ratio of a packing, which is the ratio of surface area to fluid volume in a packed bed. The phase ratio $\beta$ can be calculated by Equation (1):

$$\beta = \frac{A_{sp}}{V_{sp} + (1/\rho_{pk})}$$

* The source of this information is the column manufacturer's literature. No guarantee of the accuracy of the information can be made.
where $\varepsilon_i$ is the interstitial porosity of the packed bed, with a typical value of 0.4 for spherical particles. $A_{sp}$ is the specific surface area of the packing and $V_{sp}$ is its specific pore volume. $\rho_{sk}$ is the skeletal density of the packing, which is $2.2 \text{ g cm}^{-3}$ for silica. As we can see, silicas with large specific surface areas and large specific pore volumes have a similar phase ratio, and therefore similar retentivity, to silicas with small specific surface areas and small specific pore volumes. To obtain a true impression of the retentivity of a packing, it is therefore important to calculate the phase ratio rather than considering the specific surface area of a packing alone. This has been done in Table 1 for a range of commercial packings, for which the relevant information is available.

The three parameters, average pore size $d_p$, pore volume $V_{sp}$, and surface area $A_{sp}$ are interdependent: if two are fixed, the third one is determined as well (p. 41 of Unger$^{(1)}$). This can be expressed by the formula in Equation (2):

$$A_{sp} \approx 3 \frac{V_{sp}}{d_{po}} \quad (2)$$

This approximate formula can be used to estimate the average pore size of a packing. This is quite useful, since there are no commonly accepted conventions for the determination of the average pore size.

The specific pore volume of a silica is the key factor that determines the hardness or strength of a silica. Packings with a small pore volume are stronger than packings with a large pore volume. However, all silicas with a specific pore volume of up to about $1 \text{ mL g}^{-1}$ are quite suitable for HPLC applications and can be subjected to column inlet pressures in excess of 40 MPa, which is the common pressure limit of most HPLC instrumentation.$^{(2)}$

### 2.2.2 Particle Size

The particle size of a packing determines the chromatographic efficiency and the backpressure of columns packed with these particles. The most commonly used particle size is $5 \mu$m for analytical separations, but $10 \mu$m particles are still employed, while the application of columns packed with $3 \mu$m particles is steadily increasing. Columns packed with fully porous particles down to a particle size of $1.5 \mu$m are commercially available, but their usefulness has not yet been sufficiently explored. For preparative applications, larger particle sizes are frequently employed owing to the pressure limitation of the chromatography instrument on the one hand and the lower demand on the separation power of the column on the other.

Pressure limitations also play a role in the use of analytical columns. Commonly, the preferred operating range is at pressures less than $20 \text{ MPa}$, but most columns are stable at pressures exceeding twice this value. The pressure limitations are related to the equipment rather than the columns. The pressure needed to use a column at a particular flow rate increases with increasing column length. Also, at a given column length, the pressure is inversely proportional to the square of the particle size. This puts a general limit on the ratio of column length to particle size.

It is worthwhile exploring the properties of column length and particle size a little further. Generally$^{(2)}$ the maximum plate count of a column depends simply on the ratio of column length to particle size. Similarly, the shortest analysis time that can be reached at a given pressure limit is also simply a function of the ratio of column length to particle size. Columns with a larger length to particle size ratio achieve a higher plate count, but are slower. Columns with a smaller length to particle size ratio are faster, but have a lower plate count maximum. The particle size, together with the mobile phase viscosity and the molecular weight of the analyte, determines the analysis time at which the optimum column performance is achieved. It occurs at a slower analysis time for larger particles than for smaller particles. The analysis time at which an equal plate count maximum is achieved decreases with the square of the particle size at a constant length to particle size ratio. However, the pressure limitations of the instrumentation set a limit to both the plate count and the speed of a particular analysis, even if this optimization process is followed. An additional limit to column design has been pointed out by Halász and colleagues.$^{(3)}$ The pressure needed to pump the mobile phase through the column generates a significant amount of heat, which measurably affects retention for particles of $3 \mu$m or less.

Nearly all HPLC packings have a fairly wide particle size distribution, most commonly extending to $\pm 25\%$ around the mean. In addition, what is given as the average particle size depends on the measurement technique$^{(2)}$ and no standard technique has been established. Therefore the “$5\mu$m” particles of one manufacturer are not necessarily identical to the “$5\mu$m” particles of another. However, since the backpressure of a column depends on the particle size of the packing, this observation can be turned around and the average particle size $d_p$ can be determined from the backpressure $\Delta p$ of a column.$^{(3)}$

The procedure requires knowledge of the flow rate $F$, the viscosity of the mobile phase $\eta$ and the column dimensions, (Equation 3):

$$d_p = \frac{1000 \cdot F \eta L}{\pi r^2 \Delta p} \quad (3)$$

This very practical procedure puts the determination of the particle size in the hands of the HPLC user.
Porous particles. In addition, significant differences in the loadability of the same bed prepared from fully porous particles is over three orders of magnitude lower than loadability of a packed bed prepared from nonporous surface area of the packing. For small molecules, the mass on a column without peak distortion depends on the per column volume. The amount that can be injected fully porous particles is the significantly lower surface area major drawback of nonporous particles compared with performance, albeit at high backpressure. However, a analyses can still be achieved with reasonable column small particle size, the columns used are quite short. Fast the low permeability of packed beds prepared from such a 1.5 µm) have now become commercially available. Due to 2.2.3 Porous Versus Nonporous Particles

Both the efficiency of a column and the column backpressure depend on the width of the particle size distribution. The permeability of a column, and thus its backpressure, depends cleanly on the square of the population-average particle size. However, column performance as measured by the C-term of the van Deemter equation,\(^{(4)}\) seems to depend on the volume-average particle size.\(^{(2)}\) Since the difference between population-average particle size and volume-average particle size decreases with the width of the distribution, narrower particle size distributions are preferred over broader distributions.

The value commonly used for an assessment of the width of a particle size distribution is the ratio of the 90% point to the 10% point, often of the volumetric distribution (Figure 3). For today’s high-quality packings, this value may be around 1.5 or smaller.

2.2.3 Porous Versus Nonporous Particles

Nonporous particles with a small particle size (down to 1.5 µm) have now become commercially available. Due to the low permeability of packed beds prepared from such a small particle size, the columns used are quite short. Fast analyses can still be achieved with reasonable column performance, albeit at high backpressure. However, a major drawback of nonporous particles compared with fully porous particles is the significantly lower surface area per column volume. The amount that can be injected on a column without peak distortion depends on the surface area of the packing. For small molecules, the mass loadability of a packed bed prepared from nonporous particles is over three orders of magnitude lower than the loadability of the same bed prepared from fully porous particles. In addition, significant differences in the mobile-phase composition are required to obtain the same retention with nonporous and with porous particles. For the analysis of small molecules, the use of nonporous particles does not provide any benefits compared with porous particles.

However, the situation changes when the retention chromatography of macromolecules is considered, such as proteins and nucleic acids. For unrestricted access of molecules of a very large molecular weight to the surface of the packing, the pore size of the packing needs to be very large. Under these circumstances, the surface area available for interaction is not much larger for a fully porous packing and a nonporous packing, and quite good performances have been achieved\(^{(5–9)}\) using nonporous particles. For analytical separations of macromolecules, the use of nonporous particles makes sense. A review by Lee\(^{(9)}\) deals with the separation of proteins using nonporous sorbents.

2.2.4 Continuous Structures

The newest development in the design of separation devices are continuous rod columns.\(^{(10–12)}\) In this case, the chromatographic bed consists of a continuous porous structure with a dual pore size, containing micropores that provide the surface for chromatographic retention and macropores that provide the flow channels, like the interstitial space in a packed bed. The advantage of such a continuous structure lies in the fact that the size of the macropores can to some degree be designed independently of the size of the structural units that contain the micropores. Consequently, structures can be designed that provide a higher performance at a given permeability or a higher permeability at a given performance than packed beds can provide.

At the time of writing (1998), the practical limitations of continuous rod columns are not known, although just as in a packed bed, the structural uniformity of the rod plays a significant role in its performance. For bonded phases, uniform derivatization of the chromatographic surface needs to be achieved. While the capabilities and limitations of packed bed technology are reasonably well understood, it is not clear if the continuous rod technology gives similar freedom in the design and manufacturing of chromatographic beds of widely varying aspect ratios and widely varying surface chemistry.

To evaluate continuous rod structures (or other chromatographic devices) and compare them to packed beds, we can follow the thought process outlined by Neue on page 73 of his book.\(^{(2)}\) The chromatographic structure is treated as a black box, whose internal makeup is unknown. From the permeability of the device, the particle size equivalent of a packed bed can be calculated (Equation 3). The height equivalent to a theoretical plate
(HETP) is then measured as a function of the linear velocity. Then, the particle size equivalent is used to create the reduced plate height and the reduced velocity, just as if the device were a packed bed. In this way, all chromatographic devices are compared with each other using exactly the same framework: separation power, speed of analysis and pressure.

2.3 Chemical Properties

The chemical properties of silica vary somewhat with the preparation technique and the purity of the raw materials used in the preparation. Nevertheless, a range of general statements can be made that are universally applicable.

The surface of a chromatographic silica is covered with silanol groups, which are responsible for the polar adsorption properties of the silica, and with siloxane bridges. Several different types of silanol can be distinguished, structures (1) and (2): single or lone silanols, bridged or vicinal silanols which emerge from neighboring silicon atoms and are joined by a hydrogen bridge and geminal silanols, which are attached to the same silicon atom. Silanols are weakly acidic adsorption sites. They are also the sites at which further chemical modification of the silica is initiated.

\[
\begin{align*}
(1) & : & & \text{silanol} \\
(2) & : & & \text{single or lone silanol}
\end{align*}
\]

A fully hydroxylated silica contains about 8 \( \mu \text{mol m}^{-2} \) of silanols, or about five silanol groups per square nanometer. In water, the silanols dissociate at pH values higher than about 3. Therefore, silica is a weak cation exchanger. Consequently, the surface of a silica may contain cations unless it has been treated with an acid. If waterglass (sodium silicate) is used as a raw material, the surface of the silica may be occupied by sodium ions. Cations on the surface of the silica can be removed fairly easily by treatment with acids. However, if the cations are incorporated in the matrix, they can not be removed. Apart from sodium, aluminum or iron are common contaminants of classical silicas. The metal ions in the silica matrix affect the activity, or better said the acidity, of the surface silanols. This in turn can lead to undesirable interactions with analytes, especially in the chromatography of analytes with basic functional groups in reversed-phase chromatography. Therefore, newer high-purity silicas were developed in the late 1980s and early 1990s, based on organic silanes such as tetramethoxysilane as raw materials. Reversed-phase packings based on high-purity silicas have rapidly gained acceptance owing to their superior chromatographic performance with basic analytes. An excellent review of the influence of silica structure and impurities has been published by Cox.

When silica is heated, neighboring silanols condense and form siloxane bridges, leaving behind lone silanols. At temperatures higher than about 800 °C, most of the silanols have been removed and the structure of the silica starts to collapse, resulting ultimately in sintering of the particles. At lower temperatures, the siloxane formation is reversible and silica treated at elevated temperature can be rehydroxylated. The preparation of many silicas requires the addition of an organic polymer to influence the pore volume and this polymer is often removed by treatment at elevated temperature. Since the high-temperature treatment removes silanols, rehydroxylation of the silica surface is an important step in the preparation of many silicas. The activity of a silica depends on the details of its temperature history.

3 BONDED PHASES

Bonded phases can be broadly grouped into two categories, nonpolar bonded phases used for reversed-phase applications and bonded phases with polar functional groups that can be used in normal-phase chromatography, hydrophilic-interaction chromatography, size-exclusion chromatography, or ion-exchange chromatography. Owing to the popularity of reversed-phase chromatography, most of the work on the preparation and characterization of bonded phases has focused on this class of packings. In this section, we will first concentrate on the different approaches used to derivatize silica via silanization techniques. Classical techniques as well as some of the newer techniques will be discussed. Then the properties of specific bonded phases, their characterization and their use will be examined.

3.1 Derivatization Techniques

The preparation of a bonded phase commonly starts with a clean fully hydroxylated silica. Silanization of the surface can be carried out with chlorosilanes, alkoxysilanes, aminosilanes or other reactive silanes. The classical approach to the preparation of reversed-phase packings uses chlorosilanes in the presence of a scavenger of the hydrochloric acid by-product (Scheme 1). Inexpensive organic bases such as pyridinium or triethylamine are commonly used to remove the hydrochloric acid.

Bonded phases with polar functional groups are usually prepared using alkoxysilanes. Two approaches towards this reaction have been reported in the literature. In
the first approach (Scheme 2), the alkoxy-silane is reacted directly with the silica surface in a hydrophobic solvent such as toluene.\(^{14}\) The side product of this reaction is an alcohol, which can subsequently react with surface silanols to form an alkoxy-derivatized silica. Therefore, the alcohol needs to be removed from the reaction mixture.

\[
\text{Scheme 1}
\]

The second approach towards polar bonded phases is the derivatization of the silica in an aqueous medium. In this approach, the silane polymerizes initially and the reaction with the surface occurs in a secondary step. This is shown schematically below; the secondary step is simplified as the formation of a trisilanol and its condensation with the silica surface (Scheme 3):

\[
\text{Scheme 2}
\]

The surface coverage which expresses the molar amount of ligand of the nature of the surface is obtained when the surface of silica-based bonded phases. However, a better picture of the nature of the surface is obtained when the surface coverage which expresses the molar amount of ligand to the surface generates at least one new silanol group.

\[
\text{Scheme 3}
\]

Despite the complexity of this reaction, good results have been obtained with it. For example, the reaction of silica with glycidoxypropylsilane results in materials that are suitable for aqueous size-exclusion chromatography owing to a low level of interaction with analytes in aqueous mobile phases.

Other derivatization techniques have been reported as well. A high-temperature derivatization with hexamethyldisiloxane\(^{15}\) has been patented. The quality of the surface modification appears to be quite good. Also, other reactive silanes can be used.

The level of the surface derivatization can be assessed through elemental analysis. Manufacturers of stationary phases often report typical values for the carbon content of silica-based bonded phases. However, a better picture of the nature of the surface is obtained when the surface coverage which expresses the molar amount of ligand attached to the surface per unit surface area, is calculated. The surface coverage \(\chi\) for a monofunctional silane is calculated in Equation (4):

\[
\chi = \frac{\%C}{100A_{sp}n_{c}12} \left(1 - \frac{\%C}{MW} - \frac{1}{100} \right) n_{c}12
\]

where \(\%C\) is the carbon content obtained from elemental analysis, \(A_{sp}\) is the specific surface area of the underderivatized silica, \(MW\) is the molecular weight of the ligand and \(n_{c}\) is the number of carbon atoms in the bonded phase molecule. Equation (4) takes into account the weight gain of the sample due to the incorporation of the bonded phase. For bi- and trifunctional silanes, the weight gain correction is not quite as straightforward. Probably the best approach is to assume that the bonded phase is attached to the surface via two Si–O bonds or to measure the actual distribution using \(^{29}\)Si-CP/MAS/NMR (cross-polarization/magic angle spinning/nuclear magnetic resonance).

The silane used for the derivatization can be a monofunctional (3), difunctional (4) and (5) or trifunctional silane (6) and (7). Depending on this characteristic, the silane can bond to the surface with one or two chemical bonds. The formation of a triple bond with the surface can be excluded for steric reasons. However, with multifunctional silanes the formation of siloxane bridges to neighboring ligands is possible as well.

When a monofunctional silane is reacted with the silica surface, the surface coverage is limited by steric hindrance. Only less than about 4\(\mu\)mol m\(^{-2}\) of a monofunctional silane fit onto the surface.\(^{14}\) For difunctional silanes, a larger surface coverage can be achieved. However, it seems that the removal of surface silanols is still incomplete.\(^{16–18}\) For every silane that binds to the surface, only 1.5 silanols are on the average removed from the surface. With trifunctional silanes, the number of silanols consumed per bound silane is limited to two anyway; therefore, every trifunctional ligand that is attached to the surface generates at least one new silanol group.
Monofunctional phases are derived from silanes that can react with the silica surface through one single bond only. Many reversed-phase stationary phases are based on monofunctional silanes. The largest advantage of these phases is the reproducibility of the preparation. When multifunctional silanes are reacted with the silica surface in the presence of small amounts of water, additional silanol groups are created through the hydrolysis of the reactive group. As a consequence, the reaction can proceed further than in the absence of water. This does not occur when monofunctional silanes are reacted with the silica surface. The high reproducibility of the preparation of the stationary phases based on monofunctional silanes has been demonstrated in the literature.\(^{(26,27)}\)

A disadvantage of the use of monofunctional silanes is the ease with which the single bond to the surface is cleaved. Especially at pH values below 2, the weakest point of the attachment of the bonded phase is the Si–O–Si linkage. However, the nature of the ligand influences the stability of the bonded phase at low pH. Kirkland et al. have described\(^{(28,29)}\) a group of bonded phases that improve this problem: they use ligands with large bulky side chains that sterically protect the point of attachment of the ligand to the surface, (9) and (10).

The improvement in hydrolytic stability at low pH is excellent compared with simple monofunctional phases with methyl groups as the side chains. However, the larger steric hindrance also results in a lower coverage, exposing more silanols. Therefore, the adsorptive properties of these phases are inferior to densely coated classical phases, especially around neutral pH, leading to tailing for basic analytes.

### 3.3 Multifunctional Phases

The classical approach towards the preparation of multifunctional phases uses di- and trifunctional silanes that can bond to the surface via multiple bonds. Improvements in hydrolytic stability result at low pH. At high pH, however, the dissolution of the silica itself determines the hydrolytic stability of a phase, and therefore the type of bonded phase plays only a secondary role.
Generally, the reproducibility of the preparation of multifunctional phases is inferior to monofunctional phases and the bonding reactions need to be controlled more closely. A key factor in the preparation of multifunctional phases is the influence of trace amounts of water on the reaction. For chlorosilanes, the presence of water in the reaction medium creates a polymerization reaction, which influences the nature and the amount of ligand attached to the surface. On the other hand, water acts as a catalyst in the reaction of alkoxysilanes with silica and is an important ingredient in the preparation of bonded phases prepared from alkoxysilanes\(^\text{(16,30)}\).

Most phases designed for applications other than reversed-phase chromatography are based on multifunctional silanes. Typical examples are the propylamino phase or the diol phase. Therefore, we need to realize that the presence of unprotected and unshielded silanols plays a role in the adsorptive properties of these phases. This will be discussed in more detail in the section that deals with specific bonded phases.

An alternative approach to the design of stationary phases has been discussed by Kirkland et al.\(^\text{(28)}\). The ligands that he attached to the surface contain two reactive silanes linked by a short hydrocarbon chain (11):

\[
\text{Si-O-Si} \quad \begin{array}{c}
\text{O} \\
\text{Si-O-Si}
\end{array} \quad \begin{array}{c}
\text{R} \\
\text{R}
\end{array}
\]

(11)

It is expected that the hydrolytic stability of such phases is improved over classical bonded phases, if indeed both silicons are attached to the surface. The details of this reaction are still unknown.

Another more recent approach is the attempt to form initially a monolayer of a trifunctional silane on the silica surface followed by bonding this monolayer to the surface.\(^\text{(31,32)}\) However, the chromatographic evaluation of these materials in the literature is only sketchy. An evaluation in our own laboratory\(^\text{(33)}\) demonstrated an excellent chemical stability of the packing, but the silanol activity was very high compared with modern HPLC packings. A key assumption underlying the “horizontal” polymerization technique is the flatness of the surface, which is not given for porous packings.

The use of multifunctional silanes allows for a high coating level on the surface. Sander and Wise have shown\(^\text{(34,35)}\) that the relative retention and therefore the resolution of polynuclear aromatic hydrocarbons depends on the density of the C\(_{18}\) chains of a reversed-phase packing (Figure 4). Therefore, C\(_{18}\) bonded phases with a high coating level based on

---

**Figure 4** Separation of polynuclear aromatic hydrocarbons on C\(_{18}\) phases with different coating levels. (a) 6 nm pores, \(\sigma_{\text{TBN/BaP}} = 1.32\); (b) 10 nm pores, \(\sigma_{\text{TBN/BaP}} = 1.24\); (c) 15 nm pores, \(\sigma_{\text{TBN/BaP}} = 0.84\); (d) 30 nm pores, \(\sigma_{\text{TBN/BaP}} = 0.85\) (BaP, benzo[a]pyrene; TBN, 1,2,3,4,5,6,7,8-tetramethylnaphthalene.) (Reproduced from Sander and Wise, *J. Chromatogr. A.*,\(^\text{(34)}\) Copyright (1993) with permission from Elsevier Science.)
trifunctional silanes have found a specific application niche in the environmental analysis of polynuclear hydrocarbons.

Along the same lines, a polymeric C$_{30}$ stationary phase$^{36}$ has been developed that is capable of separating the geometric isomers of common carotenoids. Comparisons with traditional C$_{18}$ phases demonstrated the superior resolving power of the C$_{30}$ bonded phase for this class of compounds.$^{37}$

3.4 Other Approaches

There are a few interesting approaches to the design of special stationary phases that have not yet been covered in this discussion. One is the design of immobilized artificial membranes (IAMs),$^{38–41}$ consisting of a monolayer of phospholipid covalently bonded to the surface of a silica (Figure 5). The IAM derivatized silica is a chemically stable chromatographic packing that emulates the exterior of a biological cell membrane. The logarithm of the retention factor of drugs measured on an IAM column correlates well with their permeability through Caco-2 cells$^{42}$ or their absorption by inverted rat intestine.$^{43}$ Therefore, fast chromatographic methods can be used to estimate the drug permeability through biological membranes. Recently, IAM columns have been used for rapid screening of drug–membrane interactions in drug discovery.$^{44}$
